SOME POINTS IN THE DIAGNOSIS OF APPENDICITIS.[1]

BY GEORGE F. SHRADY, M.D.,

SURGEON TO ST. FRANCIS HOSPITAL,

NEW YORK.

AFTER years of perhaps unmerited obscurity the appendix has worked itself into a prominence out of all proportion to its size, but presumably with a full appreciation of its importance. Whatever may have been said of its apparent uselessness, it has at least so far demonstrated its right for attention that it has called forth the best directed efforts of advanced surgery to circumvent its dangerously erratic tendencies. Heretofore, however, the diseases to which it is a subject have been viewed so much from a purely operative stand-point that many of the other essential features of their study have been proportionately neglected. Prominent among the latter are those which bear upon the timely and correct diagnosis of the threatening as well as dangerous forms of the disease. In the face of the fact that many eminent clinicians state that it is oftentimes impossible to make an accurate estimate of the proximate or ultimate dangers in a particular case, the operator must, notwithstanding, be called upon to settle the difference when emergencies are most imperative and responsibilities most grave. In the cases which I have seen in hospital and private practice the question of diagnosis has been almost the only one which has given me any concern. In this I am well assured my experience corresponds with that of many other surgeons. In order, therefore, to clear up some of the doubtful points, I have given this part of the subject a careful and somewhat extended study, based principally upon the writings of others and supplemented by personal experience. In the attempt at a critical analysis of symptoms by an examination of over three hundred cases, I have been struck not only with the want of completeness as to detailed phenomena of symptomatology, but as to the significance of the same as bearing upon the demonstrated existence of pathological changes. My original plan comprised a statistical study of the leading symptoms, their relation with each other, and their comparative frequency of association as connected with actual lesions; but this I discovered to be impossible, unless the tables were so complicated with qualifications and loaded with explanations for important omissions, that they would be deprived of their real practical significance. Hence I have been forced to rely upon the general impressions which have been made by the multiple portraiture, and present them for what they may be worth, as a contribution to a part of the subject in which the general practitioner and surgeon are alike interested.

As every diagnosis must be based upon the study of symptoms common to other diseases, we may make a natural beginning in estimating their correlative value by glancing at a well defined picture toward which our comparisons may focus.

Let us then, with this object in view, call to our mind a case of perforative appendicitis, for it is upon the importance of diagnosticating such an one that the main purpose of this paper centres.

A young male patient, with a history of previous milder attacks, is suddenly seized, usually after a period of constipation, with chilliness, diarrhœa, reflex pain in the epigastrium, and colicky pains distributed over the abdomen. There is vomiting, slight increase of temperature, natural respiration, no marked tympanites, but general tenderness on pressure. In the course of a few hours the pain becomes localized in the right iliac region, where there is increased tenderness and circumscribed rigidity of abdominal muscles, with perhaps slight dulness on percussion. Coincident with these phenomena there is difficult micturition, sometimes tenesmus, a slight rise of temperature, to perhaps 100° F., or exceptionally 102°, and a distinct acceleration of pulse. At this stage, also, a distinct focal tenderness will be detected at McBurney's point, from one and a half to two and a half inches inside the anterior superior spine, or thereabouts, on a line with the umbilicus. Then subsequently and suddenly there is developed an intense pain in the circumscribed area, vomiting increases, abdominal distention occurs, patient shows evidence of intense shock—pinched features, cold finger tips, cyanotic lips, hurried thoracic breathing, thready, rapid pulse, and temperature 102° to 103° F. In the course of a few hours pain and tympanites progressively increase, and finally the patient dies with symptoms of septic peritonitis. This is the usual course of a classically clear case; but, unfortunately, such are subject to so many variations that they prove the exception rather than the rule.

So many unlooked-for modifications of the clinical picture present themselves that few, if any, can always be sure of these precise indications, especially during that most vital period of the earliest development of ominous symptoms, and when prompt action settles the question between life and death. The experiences of every surgeon not infrequently cross each other on these lines of mistake and doubt. So the more we examine the boundary between enthusiastic advocacy of operative procedure on the one hand, and the judicious conservatism of watchfulness on the other, the better we will be prepared to meet and treat each case as it presents itself.

Perhaps the better way to appreciate the relative significance of the usual symptoms of appendicitis is to study them in their pathological or causative relations with other associated conditions, and arrive at such approximate conclusions as may be possible under the circumstances. The first in importance and frequency of these is the localized pain in the right iliac fossa, its actual position, its degree of intensity, its time of occurrence, and its significance as indicating the character and degree of pathological lesion. I am so firmly convinced of the constancy of localized pain in the region named, that the failure to give it due importance is to be explained more on the score of imperfect examination of the case than for any other assigned reason. I expect to find it in every case, and have never met an instance in which it was absent. Whenever, after careful search, pain is not present in that situation, as is said to happen, there is always a good reason for it, even if such reason may not be discovered at the time. Thus, in the so-called fulminating varieties of perforation the system may become so suddenly overwhelmed by shock that no pain can be appreciated by the patient. The predominating pains reported as being located variously in the epigastric, umbilical, hypochondriac, and hypogastric regions are only of passing interest in helping to make a more complete and more varied clinical picture; such pains are mostly colicky and reflex in reality. It may be

[1] Read at a meeting of the Practitioners' Society of New York, December 1, 1893.

interesting to note in this connection that distinctly isolated and persistent spots of tenderness in out-of-the-way localities are not uncommonly associated with adhesive displacements of the cæcum and appendix to such situations. For instance, in three cases reported by Loomis, Clark, and Fowler, respectively, in which there was pain in the *left* iliac fossa, the appendix was displaced to that side and adherent. The varied normal positions of the appendix, as shown by Bryant and others, will greatly aid us in explaining deviations from set rules.

Since McBurney has directed particular attention to the symptomatic significance of a focal tenderness between the right anterior spine and umbilicus, the importance of more accurate examinations of the iliac region has impressed itself upon clinicians. That this painful spot is sometimes absent or not recognizable in real cases, and present in false ones, cannot be denied. Its indications have been so extensively tested, by so many observers, that there is abundance of accumulated testimony pro and con. I am not aware, however, that when associated with appendicitis it can be said to indicate any particular pathological process other than an inflammatory tenderness of the appendix itself, or a localized peritonitis in the neighborhood, either of which is made manifest by pressure at that particular point. In other words, I am led to believe that it as often indicates presumptive as it does real danger in estimating the immediate chances of the patient. It has been noticed alike in the simple cases of intra- and extra-peritoneal abscesses, and in the so called cases of acute perforating appendicitis.

The claim of McBurney, that the point indicates the situation of the base of the appendix, although a reasonable one, and, as far as my observations go, a just one, is denied by Kelynack[1] "after an examination of a very large number of cases." It is certain, however, that when the focal intensity of appendicitis is in the situation indicated, the explanation is sound. This was proven absolutely in three of my recent cases of perforative appendicitis, and in one of the recurrent variety operated upon in the interval.

I have also noted the presence of the painful point when the appendix was relatively far away, being posterior and external to the cæcum. Whatever relation it may have to actual lesions, when the point can be demonstrated, it is a valuable diagnostic sign.

It would appear, from our present knowledge and in the light of accumulated experience, that the real cause of tenderness is in the appendix itself. Whether the organ is situated immediately under the painful point or not, the pressure is either direct or communicated in such a manner that the tender and diseased appendix is caught somewhere in the line between the finger-point and the posterior abdominal wall.

In this connection I may state that my attention has been called by Dr. Edebohls to the possibility of diagnosticating recurrent appendicitis by actually feeling the appendix through the abdominal wall, and demonstrating the cause of tenderness by direct pressure upon the organ. In one case I was able to do this, to recognize the appendix rolling under the fingers, to limit tenderness to direct pressure upon the process, and afterward to remove the organ by operation from that exact locality.

If we assume that pain on pressure indicates inflammatory lesion at or near the point of pressure, we must take the chances of other organs in the neighborhood likewise affected giving the same sign. Fortunately there are very few pathological conditions other than those which belong to the appendix itself which make mistakes probable.

One of the earliest local symptoms after pain is that of circumscribed muscle tension in the right iliac fossa. This occurs in about forty per cent. of the cases, although its absence is not noticed in the remaining sixty per cent. In eighteen acute cases in which it was looked for, I found it in every one. Thus I have been led to rely upon it as an exceedingly valuable sign.

Tumor in the iliac region rarely shows itself before the third day after the appearance of localized pain or tension, and not until agglutinating or circumscribed effusions have occurred. As tumor generally indicates nature's effort to limit effusion, its size, situation, and firmness are important matters to take into account. Swellings which form slowly are firm and distinctly circumscribed, are not so liable to rupture as those which are more diffused, rapidly enlarge, and are attended with marked constitutional disturbance—such as sudden rise of temperature and pulse, rapid increase of degree and area of tenderness, and progressive meteorism.

That the tumor, even in bad cases, is not always due to limiting effusions, was proven in a girl, aged nineteen, upon whom I did appendectomy for Dr. D. St. John, of Hackensack, N. J. Before the operation the swelling was so distinct, tender, and circumscribed that we were sure an abscess had formed. On exposing the site of the swelling the latter proved to be nothing more than a thickened cæcum distended with fæces. In that case the appendix was found perforated and adherent posteriorly. Not infrequently tumor is entirely absent, especially in those cases in which the inflamed appendix is situated behind the cæcum; but as a compensatory advantage in diagnosis, local rigidity of the abdominal muscles is generally quite marked in the bad cases, as well as the existence of focal tenderness.

Dulness on percussion is rarely recognized before the fourth day, and being a comparatively late symptom, is merely confirmatory of limiting inflammation with more or less extensive effusion of lymph or pus. When the abscess is behind the cæcum, dulness can rarely, if ever, be demonstrated. Fluctuation does not appear as a rule until the second week. It is often difficult to demonstrate, is sometimes recognized by rectal examination, but when present removes all doubt as to the necessity of immediate operation for abscess.

Œdema of the overlying integument is not noticed until a paratyphlitic abscess has formed, of which it is a reasonably sure indication. Hence for purposes of early diagnosis in apprehension of danger it is of no value and cannot be expected until late in the disease.

Although a bad case of appendicitis gives rise ultimately to formidable conditions, the pulse and temperature do not indicate such probabilities at the commencement. The explanation is sought for in the necessarily limited degree of the initiative lesion, and the correspondingly small area of peritoneum that is primarily involved. In some of the worst cases the temperature has been reported normal until the quick ending of the case in overwhelming shock.

Generally, however, the pulse is slightly accelerated, averaging a hundred, and the temperature is above the normal—from 100° to 101° F. The significance of dangerous conditions is the gradual increase of both in connection with the augmentation of pain, of tenderness, and tympanites. Often the suddenly increased pulse-beat is the earliest bad symptom, preceding even the ominous rise in temperature, the extra intensity of pain, and the rapid, grunting respiration.

Usually, however, before a steady progression to the bad, there is a deceptive calm, in which pulse, temperature, and pain decline, marking the occurrence of effusion and the decrease of tension of inflamed parts.

Vomiting is an early symptom, and variously marks the reflex indication of commencing inflammation, or the occurrence of perforation, especially the latter; when it becomes greenish in character it is associated with a chill.

The sudden occurrence of intense localized pain usually indicates a dangerous change either in the occurrence of perforation or the tearing of adhesions and rupture of an abscess, and when combined with shock indicates effu-

[1] Pathology of the Vermiform Appendix, by T. N. Kelynack, M.D., London, 1893, p. 149.

sion in the peritoneal cavity. The extent of effusion is governed by the condition of tension, amount of contents, mobility, and length of the appendix. Fortunately, the anatomical relations of the parts are such as tend to limit the area of invasion of surrounding parts; contrasting strongly with perforations elsewhere in the abdominal cavity. Kelynack offers the following explanations, which carry with them a more comforting assurance of relative safety than is usually entertained:

1. A small quantity of the contents of the appendix is extravasated. 2. The extravasated materials are usually solid. 3. The material is of a less irritating character than from other portions of the intestinal canal. 4. The position of the appendix interferes with the rapid diffusion of the effused material. 5. The movements of the appendix are more or less limited.

Taking our chances of making a correct and timely diagnosis in the dangerous cases of appendicitis, many possible conditions must be taken into account as associated with the symptoms of other simulating diseases.

The first of these is ordinary typhlitis or cæcitis. This affection is far more common than is generally supposed. Although at its commencement showing ominous symptoms, it always tends to recovery under proper medical treatment. With this condition an early pronounced swelling, usually oblong in shape, is the rule, with some tenderness on pressure; no increase of temperature nor of pulse, constipation, rarely vomiting, no chill, no localized rigidity, and a chronic history, in a person past middle life. Frequently indentation can be made in the tumor on account of its fecal contents. The symptoms are not progressive in severity, and there is no acute pain on deep pressure. Whether or not it is true that in the large majority of these cases a simple appendicitis is the initial lesion cannot be proven; as such, as a rule, recover, even without an operation. It is quite probable that many cases of simple catarrhal appendicitis recover without showing subsequent lesion, although within the first forty-eight hours they may present significantly dangerous symptoms.

In one exceptional case, which I have previously reported, there were four distinct attacks so closely resembling suppurative appendicitis that on each occasion an operation was contemplated; but on the patient dying of another disease, no autopsical lesions of the appendix or cæcum were discoverable, save a general thickening of the latter.

The practitioner who is called to a case of pain and swelling in the right groin, and would not at once think of appendicitis, can be stamped as one who does not take a medical journal, does not attend his medical society, and does not read the daily papers. Still, very many mistakes are recorded, in the attempted diagnosis of appendicitis, when swelling, or tenderness, or both appear in the right iliac fossa. These mostly refer to psoas abscesses, morbus coxarius, renal and biliary colic, tubal and ovarian disease, intussusception, malignant tumors of colon or cæcum, perinephritic abscess, typhoid fever, and even floating kidney; while in the acute and grave cases, where sudden peritonitis appears, perforating ulcers of the stomach or intestine, and rupture of the gall-bladder, have been mistaken for perforation of the appendix.

The differentiation of these, in the order mentioned, can be done by comparing their salient symptoms with those of the disease under consideration.

Psoas abscess is chronic in character, the tumor is slow in development, is generally tympanitic on percussion owing to its deep seat, has a doughy feel, caries of the lumbar spine exists with spinal tenderness and deformity. The right leg is drawn up, and is usually the first sign of trouble, the patient is cachectic, and the developing abscess shows a low grade of action with attendant hectic fever. The maximum of pressure tenderness is lower and more external than in appendicitis.

Dr. H. C. Coe communicates a case of psoas abscess, however, in which McBurney's point was distinctly marked, and in which all the other essential features of appendicular disease were present.

There is at present in my wards at St. Francis Hospital a case of undoubted psoas abscess, in which the tender point is distinctly marked on a line between the anterior superior spine and the umbilicus. This may be an instance in which appendicular disease antedated the abscess in question, but such is scarcely probable in view of a previously long existing deformity of the lumbar spine.

Renal and biliary colic are ushered in with very severe symptoms of localized pain and vomiting, but there is no localized iliac tension, no tumor, no focal tenderness, and no significant shock. The intensity of the pain in biliary colic is situated, as a rule, in the epigastrium, is intense and stabbing in character, extending backward toward the right scapula, and is followed by jaundice: while in renal colic the same intensity takes the direction backward to the lumbar region, and downward along the cord, retracting the testicle.

It is quite true that occasionally in appendicitis the pain is along the cord, and is sometimes attended with difficult micturition and retraction of the testicle: but the focal centre of tenderness, when carefully sought, is almost invariably at or near the situation of the appendix. In renal as well as biliary colic the intense and spasmodic pains are limited to the affected side, and are not attended with elevation of temperature, increase of pulse, or tympanites.

The diagnosis of appendicitis in the female is attended with peculiar difficulties bearing on the differentiation of symptoms associated with tubal and ovarian disease. Coe, Grandin, and others have shown that the painful point and tumor are below the situation of the region of the appendix, the swelling is rounder, nearer the uterus, and more circumscribed, and its connection can usually be traced to the tube or ovary by rectal or vaginal palpation. When, however, the latter cannot be done the absolute diagnosis is often left in doubt. Usually, however, the previous history of menstrual troubles, the chronic character of the case, and the absence of the recognized symptoms of recurrent appendicitis will help to a conclusion. The latter are so well described by Bull, in a recent paper read before this Society, that it is unnecessary to refer to them in detail. In the acute forms which sometimes are associated with the puerperal state, the symptoms and their sequence must be studied with great circumspection. The same may be said of hæmatoma, two remarkable and instructive cases of which have been reported by Barker, in which it would appear that the ordinary means of distinction known at the time were of no avail in avoiding the error.

Intestinal obstruction is not infrequently mistaken for perforation of the appendix. Ransohoff records twelve instances, and Hartley two, in both of which operations were undertaken for what was thought to be strangulation. I had one such case, the error of which was not discovered until a gangrenous appendix was found. But under such circumstances there is no question as to the propriety of resorting to operative interference, not only to clear away all doubt, but to give the patient the last chance. Usually the suddenness and severity of the attack without increase of temperature, the rapid distention of the bowels, the grunting respiration, the fecal vomiting, great prostration, tenesmus, the absence of localized pain and tumor, with diffused abdominal tenderness, will complete the clinical picture.

In intussusception the tumor can generally be recognized, oblong in shape and following the course of the colon, one side or the other, without marked local tenderness or increase of temperature, and there is besides a rectal discharge of bloody mucus, a rare symptom in appendicitis. Intussusception is essentially a disease of children, occurring in eighty per cent. of the cases before the tenth year, and in a large proportion of these the tumor can be felt through the rectum.

In suppurative appendicitis it is not uncommon for the paratyphlitic abscesses to burrow their way to the kidney

or liver, and may even perforate the diaphragm. Under such circumstances, with a fluctuating swelling high in the lower or lumbar region, it might be easy to err as to the origin of an abscess. In one of my cases of burrowing appendicular abscess, an escape was found through the foramen ovale in the inside of the thigh. But abscesses of this nature require time for their production, and can hardly be mistaken for lesions requiring such urgent and immediate treatment as those previously mentioned. In this connection I take occasion to refer to the admirable paper of Weir on the subject of sub-diaphragmatic abscesses of appendicular origin, in which many interesting diagnostic features are very instructively presented.

Within the past two years I have been asked to do appendectomy on two cases which proved to be typhoid fever, and upon which, of course, I did not operate. One is a well-known journalist of this city, who never tires of talking of his escape, the other occurred in a boy aged sixteen. In the first instance the patient had been ill a week with slight fever, pain and dulness in iliac region, and tenderness over a distended abdomen. No focal point could be discovered. His furred tongue, headache, unnatural stupidity, rapid pulse, and characteristic diarrhœa, suggested the idea of studying the temperature curve, the ultimate result of which was equally satisfactory to the family physician and consultant. In the case of the boy the symptoms were ushered in with colic, chill, vomiting, headache, and abdominal pain. The physician in attendance having the night previous listened to the danger of appendicitis, graphically detailed in a paper before the Academy, became convinced his patient was afflicted with that disease, and demanded immediate consultation. It was with much difficulty, and with some misgiving on my part, that an opposite view was taken, but the typhoid took its course and the boy still carries his appendix.

From conversation with some of my medical friends I learn that the suspicion of appendicitis is not by any means uncommon with cases of commencing typhoid. It does not, however, seem very difficult, under the circumstances. to make a correct diagnosis, when the great frequency of the pulse, the increased elevation of temperature, the headache, and characteristically furred tongue are duly taken into account. Still the best of men have been mistaken when iliac pain and local tenderness appear to be at first the leading symptoms.

It is not to be denied that perforations occur as the result of typhoid ulcerations of the appendix, but these are not only very rare, but do not take place until comparatively late in the disease, and when there is no question generally as to the character and significance of the previous symptoms.

Neuralgia of the iliac fossa is a condition associated with localized pain only, is intermittent in character, and is relieved rather than increased by deep pressure. Yet I know of one instance—naturally a medical man—in which the radical operation was done for just this condition, but fortunately with the ultimate recovery of the patient. He has no appendix now, and can graciously patronize those of his acquaintances who are not so fortunate in being rid of a quarrelsome and non-insurable tenant.

Gibney has called attention to the possibility of mistaking cases of perityphlitis for hip diseases. Although the cases cited by him point in that direction, it is ordinarily not difficult to discriminate between the two diseases, notwithstanding the marked flexion and abduction of the thigh which may occur in both. Hip disease has a long and characteristic antecedent history, and the focus of pain is in the hip-joint itself, directly occasioned by flexion and rotation of the thigh and by crowding the joint surfaces together.

One of the older means of diagnosticating appendicular abscess by aspiration is now out of vogue. While in some exceptionable cases it may be the only sure way of making a diagnosis of an existing intra- or extra peritoneal abscess, it is liable to do great mischief when pus is found, septically infecting the peritoneum on the withdrawal of the needle. Although I have often made the exploration in times gone by without accident, I never find it necessary now, except perhaps when forced to settle a doubtful point during the actual progress of a laparotomy. Aside from its danger it is not reliable, as we often fail to find pus when it is afterward demonstrated to be present by the safer and surer method of free exposure of the diseased parts.

I have not thus far referred to rectal examinations for diagnosis, as personally I am somewhat in the position of the historian who wrote the famously brief chapter on the snakes in Ireland. I have not often seen the necessity of practising it except in women, and when I have done so the results have not been brilliantly confirmatory. In some cases it will aid us, but in most it will not. Loomis urges early rectal examinations under ether, with a view of detecting small circumscribed effusions in the iliac fossa. I confess, however, that I could not trust my touch to such a delicate test in clearing up an otherwise doubtful point. And besides, the force and pressure necessary in the bimanual examinations might tear protecting adhesions, or possibly rupture young and tender abscesses.

It would scarcely be possible to enumerate or classify the number and variety of cases in which obscure and suspicious symptoms of appendicitis may exist. Every practitioner at times thinks of them and eliminates them as best he may, proving in his own mind, by increased experience, that very much is to be learned in this particular part of the inquiry.

It is with a view of contributing to more certainty of distinction in suspected cases, and in noting some of the differences between the mild and recoverable cases and the severe and fatal ones, that the suggestions based upon the personal experience of the writer are offered. There is now no question how we should operate but when. In clear cases no time is to be lost. Under such circumstances there is no operation for emergency that has a better record. In the doubtful cases the line has not yet been drawn absolutely between watchful patience and unwarranted exploration, and it will not be until our means of diagnosis are more patiently perfected and the relatively significant symptoms in their proper sequence are still more carefully studied.

8 East Sixty-sixth Street.

Pre-natal Determination of Sex.—Dr. T. O. Keator, of Accord, N. Y., writes: "In your issue of December 16th, I notice an article by Dr. Abbot, of Hamburg, N. Y., on pre natal determination of sex. It reminds me that some years since I had been making great efforts to determine the sex prior to delivery, and thought that I had succeeded; and was so well convinced that conception just prior to menstruation would surely result in a boy, and just after a girl, and had an article written for publication on the subject, when I was called to attend Mrs. S—— in confinement, and in a few hours delivered her of a pair of twins, one boy and one girl, I began to think that there was something wrong with my theory, and consequently never published my article. Since that time I have made diligent inquiry wherever it was possible that the time of conception could be known, and out of ten cases where there could be no mistake about the time of conception, six conceived just after a menstrual period, and produced four boys, two girls; the other four conceived just prior to a menstrual period, and produced three girls and one boy. In pursuing this subject I think most physicians reach their conclusions too soon, and from too few cases. We are as far from pre natal determination ot sex as ever, unless someone will explain the twin conceptions of one male and one female."

Trichloracetic Acid in papillomata, warts, and in papillomatous urethritis.—Lauz.

APEX CATARRH.

By HORACE S. STRAIGHT, A.M., M.D.,

CLEVELAND, O.

LECTURER ON DISEASES OF THROAT AND NOSE, MEDICAL DEPARTMENT, WESTERN RESERVE UNIVERSITY, ETC.

Apex catarrh is the name I have chosen to designate a certain condition of the lungs occurring most often at the apices, but next in frequency in the lower portion of the subclavicular region or upper portion of the mammary region. Localized capillary bronchitis would describe the condition in its earlier stages, but in well marked cases there is a wider involvement of tissue. I know of no term that describes the condition better than the one chosen—apex catarrh. If there is any literature upon this subject, it has never been my good fortune to find it. For years I have ransacked all the literature at my disposal, only to find no mention at all of any such condition. Nearly all writers speak of a long period of depressed health that precedes tuberculosis of the lungs, but there is nothing told us of the symptoms or physical signs found in the condition of lowered vitality. It is with this period of depressed health that this paper has to do.

Etiology.—There is little to say concerning the causes of apex catarrh, because in the five years since which time my attention was called to the frequent occurrence and importance of this condition, I have learned little as to its etiology. Those causes ascribed by the various writers as factors in the production of tuberculosis of the lungs, certainly have an influence in the production of an apex catarrh, and yet in the great majority of cases one can find no adequate reason. Apex catarrh does not occur simply in people whose health is depressed, whose occupation is in-door, and whose surroundings are unhygienic.

Many such cases occur, but I see many cases in people who are apparently in the best of health, and I am constantly surprised to find evidences of slight catarrh at the apices of people who are not anæmic, who have not lost flesh, and who complain simply of stomach disturbances and of feeling tired. From the first appearance of the grippe until one year ago, I saw more cases of apex catarrh than ever before or since, and yet before the grippe appeared, my dispensary service was overflowing with cases of apex catarrh, and there is no change at the present time. It occurs most often in people under forty years of age. I have never seen a case in a child less than four years of age. It is of frequent occurrence in children, but presents marked differences in its symptoms and course. The greater number of cases occur in people under thirty-five years of age.

The disease may originate in two ways. The patient often comes under observation when suffering from an acute cold. His history in the majority of cases discloses the fact that even before taking the acute cold he had not felt well, that his appetite had not been as good as usual, that he had felt tired mornings, and also had tired easily upon exertion. This enumeration enbraces only a few of the more prominent symptoms.

My opinion is that the patient was in a lowered constitutional condition, and that his acute cold was contracted because of his lowered vitality; that there was a catarrhal condition of his capillary bronchial tubes at the apex, before the onset of the cold which brings him to the doctor. While the patient always persists in ascribing all his future sufferings to the cold he caught at a certain time, my experience has taught me that the acute cold only brought the patient to a realization of his condition in the greater number of cases, and that the acute cold had little influence in the future of his case. I do not mean to say that a healthy person may not take cold; what I mean to say is, that a patient suffering with an apex catarrh takes cold much more easily than a healthy person, and that his sufferings are out of all proportion to anything that can be detected in his case. If patients who take cold easily and on whom colds make a marked impression, were subjected to a careful chest examination, the explanation of the patient's tendency would more often be found than in ascribing it to malaria, rheumatism, gout, etc.

Many a case has passed under my observation that would not believe that there was anything at fault—patients at whose apices I had detected the early signs of an apex catarrh—until an acute cold would bring them back to me weeks after my first examination. I see many cases of this kind during the summer months, when the tendency to take cold is not so great. I have no explanation to offer as to the reason why the apex catarrh develops. That the condition does occur as stated, is a conviction only arrived at after six years' observation. Another class of cases develop in connection with an acute cold. If the condition is a simple catarrh—and this is my belief—it is reasonable to believe that the inflammation may attack not only the mucous membrane of the nose, throat, and large bronchial tubes, but also the mucous membrane of the capillary tubes in the subclavicular region; why this should occur in one case and not in another is impossible of explanation. When this does occur the inflammation may subside in every other region previously involved, and yet continue to spread at the apex. This is the best explanation of the second class of cases that I have been able to find.

In the slightest cases there is undoubtedly an inflammation of the mucous membrane of the capillary bronchial tubes. In the well marked cases there is in addition an inflammation of some of the air-cells of the lung. The inflammatory process may even spread to the pleura. This condition is undoubtedly catarrhal. There is no other supposition that is as reasonable, in view of the course of the disease and the large proportion of recoveries. It seems to me untenable to consider an apex catarrh a localized tuberculosis. A small number of cases that have the same physical signs as an apex catarrh, are tubercular from the beginning. The catarrh is in these cases due to the irritation of a previous deposit of tubercle. The statements in the last two sentences are commonly accepted, although no explanation can be given. These cases are only frequent enough to prove them an exception to the supposition that cases of apex catarrh are simply catarrhal. That an apex catarrh may become a localized tuberculosis or an incipient phthisis, is a reasonable conclusion. It is in view of this possibility that the importance of these early catarrhal conditions is emphasized. The tubercle bacillus does not grow even if it gain entrance into a healthy lung, but if it gain entrance into a portion of the lung that has become depressed in its vitality through a catarrhal process, the conditions for growth and development are favorable. Why this infection with tubercle bacilli occurs so infrequently is a mystery to me. It might be explained by assuming that the catarrhal process must become marked before the non-resistance of the cells is great enough to permit of their growth. It is a fact that the larger number of cases never become marked. In the early cases of apex catarrh there is no expectoration. It is impossible to obtain any sputa for examination, unless the patient have a new cold, and then the expectoration arises from the larynx or pharynx, and not from the area of chronic capillary bronchitis. For this reason I have never made any extended observations with the microscope in slight cases. In many marked cases of apex catarrh in which I suspected infection from tubercle bacilli and made a microscopical examination, I have failed on repeated examination to demonstrate their presence.

The objective symptoms may be very few. In many early cases there is no anæmia, although an anæmia may develop in spite of an early diagnosis and treatment. The earliest symptoms are usually disturbances of the gastro-intestinal tract. The tongue becomes slightly coated, the patient complains of a bad taste in his mouth on rising, he loses his appetite, and suffers more than ordinary from constipation. Patients often suffer from peculiar sensations in the stomach. These neuroses seem

to occur most often when the stomach is empty, and may be relieved by taking food. They are frequently referred to as "such a gone feeling in the stomach." Frontal headache is a frequent symptom. It is dull in character. This headache is liable to be complained of most in the earlier part of the day, but it may be almost continuous. Patients who are subject to sick headaches, upon the development of an apex catarrh suffer more severely from their headaches. The attacks are not only more severe, but they occur more frequently. The possibility of a frontal headache being a symptom of an apex catarrh, is a growing conviction on my part. It may be said that this headache is the result of the gastro intestinal disturbance. All this I grant, but the point insisted upon is that the gastro-intestinal catarrh is an associated condition, and that the apex catarrh is not developed as a result of the malassimilation of food. In other words, apex catarrh is the name given to a disease in which all the organs supplied by the pneumogastrics suffer. It could possibly as well be called a condition in which all the mucous membranes suffer. The primary condition at the apices is certainly limited to the mucous membrane of the capillary tubes. The mucous membrane of the digestive tract is also markedly involved. Even the mucous membrane of the genito-urinary tract shows evidences of disturbances in frequent urination and at times traces of albumin.

The most marked symptoms are often those of the gastro intestinal mucous membrane, and yet in the earliest cases even slight changes can be detected at the apices, with slight rise of temperature and slight rapidity of pulse. These early signs may be only a transference of heart-sounds, and yet they are most important, because such cases, if the apex catarrh pursues an unfavorable course, die of tuberculosis of the lungs. If the physician could be assured that a given case would recover, it would make little difference as to the name given to the condition, but the prognosis and treatment certainly are dependent upon an appreciation of all the organs involved. In a certain number of cases there is a marked functional disturbance of the heart, and pain in the cardiac region is a frequent symptom. At other times the patient shows marked signs of liver disturbance, and patients are apt to think they are suffering from a simple biliousness The early signs at the apices are not easy to detect. It takes much study and care to be at all certain. It sometimes takes a number of weeks' observation to arrive at a positive opinion, although, as a rule, one can decide upon first examination.

The gastro intestinal symptoms are plain. The patient has made the diagnosis himself, and will not believe in any other opinion.

The case is treated symptomatically. The great majority do well upon such treatment. Many recover if not treated at all. If the patient fails to improve, and months after coming under observation the chest is examined and catarrh at the apices is found, the condition is explained as being due to the long-continued malassimilation of food. I do not pretend to deny that this explanation might not apply in exceptional cases, and yet I do maintain that the great majority of cases do not arise in this way.

The subjective symptoms are much more severe than the patient's appearance would lead one to think. Patients complain but get little consideration, because they do not look sick. They complain of being so tired. Tney are apt to feel worse every other day. For this reason they are often thought to be cases of malaria. Malaria is almost unknown in Cleveland, and with this statement I leave the discussion as to this possibility.

Patients complain of aching all over the body. They tire easily upon exertion, and complain of oppression in the upper anterior part of the chest. Nervousness is a frequent symptom. Pain under one shoulder blade, or between the scapulæ, is almost certain to occur at some stage of the disease. Pain in the lumbar region is also a marked symptom. Patients suffer more upon damp, cold days, or if they take cold.

The tendency to take cold is striking. While a slight cold may produce little change in the patient's appearance, his suffering is out of all proportion to anything that can be detected. The pulse may not be increased in frequency. The temperature may not rise even one-half of a degree. Other cases when they take cold have a marked rise of temperature and a rapid pulse, and have many symptoms in common with typhoid fever. The differential diagnosis between a case of apex catarrh with an acute exacerbation from cold and typhoid fever, is not an easy matter. It can, however, be decided in most cases within a few days. The patient who takes cold easily and on whom colds make a marked impression, ought always to be subjected to a chest examination, and the whole matter is often thus explained by the detection of a smouldering capillary bronchitis at the apices. Painful spots in the upper anterior portion of the chest are often complained of. Intercostal neuralgia occurs at time in most cases.

One of the earliest symptoms is a morning depression. After 10 A.M., the patients feel better, and they almost always feel best late in the afternoon. While in the well-marked cases the patient suffers much more than his appearance would lead one to think, the early cases often think there is nothing at all the matter, and that they need no medicine. Many a patient who came to me for some local disease of the upper air-passages, and at whose apices I discovered the key to the condition for which he sought advice, and prescribed with reference to this fact, has told me, after taking his medicine for a week or two, that he felt much better than when he first came under observation, although at that time he had reported himself perfectly well. When asked why they had not stated their real condition at first, they invariably say, "I did not know that I was not as well as usual, but I feel so much better now that I must have deceived you as well as myself."

Physical Signs.—Upon inspection: In the early cases nothing may be found upon inspection. In cases that are at all well-marked one can often detect a pallor of the skin, also a localized congestion of the superficial veins. Ordinarily the expansion is normal, as well as the frequency of the respirations. On forced breathing in marked cases one shoulder blade may not move as freely as the other, and depressions in the subclavicular and mammary regions may occur.

Upon percussion: In slight cases there is no change to be detected by percussion, but slight increase in the resistance can often be detected, although there is not consolidation enough to raise the pitch of the percussion-note. A localized tenderness is often complained of during percussion, or the patient may tell you that his chest was painful for some time after the examination. In well-marked cases, the pitch upon percussion is higher than normal.

Upon auscultation: Transference of heart sounds only may be found. If transference of heart-sounds is found, a positive diagnosis can be made although the patient may have no elevation of temperature or rise in the pulse-rate. As a rule, a temperature of 99.5° F. is found in cases in which transference of heart-sounds is detected. The pulse is usually slightly increased in frequency, although the rise of temperature occurs earlier than the disturbance of the pulse. It is also the rule, in cases at all advanced, to find irregular breathing as well as transference of heart sounds. Diminished respiration also occurs. Subcrepitant râles may occur in connection with the foregoing signs; but râles of any kind are rare, unless the patient has taken a fresh cold. In cases of apex catarrh, I have never been able to detect any special changes in the extreme apex—the supra-clavicular region—except at times a slight rise in pitch upon percussion.

Whenever I find persistent fine crepitation, I suspect that the case is one of incipient phthisis. Rough breathing also is a common sign.

Temperature and Pulse.—The temperature is usually slightly elevated, ranging from 99° F. to 100° F. A temperature of 99° F. does not necessarily mean anything, and yet, if it occur in the earlier part of the day and is persistent, it ought to be taken at night. The temperature in the early morning may be subnormal. This is liable to be found in the cases characterized by great depression. Any persistent elevation above 99° F. I consider febrile. A small proportion of cases have a normal temperature and pulse through the whole course of the disease, unless they take cold. The pulse ordinarily is about 90° F. The tension is usually less than normal. Irritability is a noticeable feature. Irregularity is of frequent occurrence. Intermittency is rare, but may occur.

The duration of these cases is something that it is absolutely impossible to prognose. The truth of this statement is the more impressed upon me as a larger number of cases pass under observation. The local lesions spread for a time in spite of treatment. Such a case ordinarily has an implication of both apices before he recovers. An early case may have only the slightest signs at one apex, but almost without exception, the lesion spreads to the other apex, although creosote may have been given as soon as transference of heart-sounds was detected. A fair average of duration is from three to six months. Many cases last for years. Many cases recover sufficiently within a few weeks to stop their medicine.

After taking treatment for a short time the patient feels perfectly well, and in spite of being advised to continue because the local lesion has not closed up, the patient discontinues treatment—in many cases only to find out within a short time that all his old symptoms have returned.

An apex catarrh often occurs in connection with some other disease whose presence so completely explains the patient's condition that the apex catarrh is overlooked. The case may fail to improve because the apices receive no attention, and yet so many cases of chronic disease fail to respond to treatment, that the fact of itself may not cause any suspicion in the attendant's mind.

An apex catarrh often occurs in connection with secondary syphilis. I have seen a number of such cases that had had the wisest possible treatment for the syphilis, but whose sufferings were so much like those of some apex case that I had helped, that they abandoned their doctor and came to me.

With no change in the specific treatment except the addition of creosote or benzoal, I have seen these cases improve promptly after months of suffering. I have often seen cases of an apex catarrh in a patient with organic heart disease. If a patient with a sound heart should develop an apex catarrh—and this is a matter of daily observation—why should not a patient suffer from the same disease who is also suffering from an organic heart lesion?

The greater number occurred in patients with organic heart disease, whose conformation was perfect. Patients with healthy hearts, in whom a catarrh at the apex develops, complain in at least half of the cases of their heart-action. The majority of cases with organic heart disease experience occasionally on exertion a palpitation and irregularity. With the development of an apex catarrh the patient suffers much more from his heart. The physician discovers a murmur upon examining the heart, and the condition so thoroughly explains the course of the patient's sufferings that he is given digitalis and tonics, and then when he fails to improve the reason is hard to explain. If the temperature were taken, the practitioner would be led to see that there was some other condition present. A slight case of apex catarrh in a patient who has organic heart disease with a loud murmur, is often exceeding difficult to diagnose, because the heart-sounds are changed, and in early cases the transference of heart-sounds is the most important physical sign.

Apex catarrh occurs also in connection with chronic disease of the joints, and I have seen many such cases. The surgeon expects to find anæmia, loss of flesh, etc., in connection with hip-joint disease, knee-joint disease, and Pott's disease. He gives cod-liver oil and tonics and treats the local condition, and if the patient does not die of phthisis, he never realizes that there ever existed any disease at the apex. If such a case does die of tuberculosis of the lungs, what shall we say? That the patient developed tuberculosis secondary to the chronic local condition, or that the lesion in the joint and the apex occurred at the same time, due to some unexplained constitutional state; and that one lesion—the joint—ceased to progress, and that the other—the apex—continued to spread, and cost the patient his life? This seems to me to be a fruitful field for investigation. I have seen many cases of enlarged cervical glands that occurred in adults and children in connection with an apex catarrh.

I have also seen an enlargement of the inguinal glands occurring in the same connection, although less frequently. Apex catarrh also often develops in asthmatics and patients suffering from chronic bronchitis and emphysema. They suffer more than ordinary, and present themselves for treatment. They are easily overlooked, because an early apex catarrh or a developing catarrh at the apex is difficult enough to diagnose when no other disease of the chest is present; but in connection with asthma or emphysema, it is sometimes impossible to decide. When in doubt, treat the asthma as you would if you were certain no catarrh at the apex were present, and give the patient creosote. You can make no mistake, for creosote is as good a remedy in chronic bronchitis as any I know, and the best thing for an apex catarrh. A short observation of the temperature will probably enable you to decide; also remember that the apex catarrh, if present, is surely going to spread for a few weeks in spite of any treatment, although the patient's general condition may begin to improve within a few days.

Treatment.—The treatment may be summed up in a few words. Give the patient creosote, guayacol, or benzoal, and treat him otherwise on general principles. In the cases that suffer from marked gastro-intestinal disturbances one certainly obtains better results by giving also pepsine, stomachic tonic, dilute acids, etc. I have often been asked as to the administration of creosote in phthisis. In incipient phthisis I always make a trial of creosote, but in those cases in which tubercle bacilli are found in the sputa, the patient usually fails to respond in a satisfactory way to any treatment. It is in apex catarrh that creosote acts most brilliantly. It is in those catarrhal conditions the most valuable remedy with which I am acquainted, and when benzoal appeared—a pleasant remedy that can be given to children and fastidious patients—the difficulties attendant upon the administration of creosote were largely removed.

For at least five years I have realized the frequent occurrence of apex catarrh in adults. It is only within the last two years, however, that the frequency of the occurrence of this disease in children has been impressed upon me. The reason is not difficult of explanation. For five years I was chief of the throat and chest department of the John Huntington Dispensary. My service was almost entirely limited to patients over fourteen years of age. The chief in charge of the children's department classed and treated every case under fourteen years of age. For this reason my opportunity was almost entirely limited to my private practice. My private practice was never large. I had plenty of office patients, but they were mostly adults. I have only arrived at my knowledge of apex catarrh in children through many a humiliation. I really thought for two or three years that if a patient was less than twelve years of age the occurrence of an apex catarrh was out of the question.

The importance of an examination of the chest in the slight febrile condition of children is what I hope to impress upon the readers of this article. A case or two at this point may be helpful.

Case I.—One year ago last March, a little girl aged

six came to my office complaining of frontal headache. Her pulse was 120. Her temperature was not noted. Her tongue was slightly coated, but there was nothing in her condition that led me to think the case more than an ordinary biliousness. I gave her tonic doses of quinine and one twentieth of a grain of calomel every two hours. In four days she returned. She complained as much as ever. Her pulse was rapid, but I attached little importance to this fact. The quinine was continued. Again she returned with the same story, only to be ordered to continue her quinine. After two weeks of treatment and continued complaint of frontal headache, the possibility of eye-strain suggested itself. I had finished writing a note to an oculist requesting a test of vision, when the possibility of the headache being a symptom of an apex catarrh also suggested itself. Her temperature was now taken. It was 100° F. Her pulse was 108.

Her chest examination revealed a slight catarrh at the right apex. The quinine was discontinued, and single-drop doses of creosote every two hours were given instead. Her headache disappeared within a few days and did not return. She continued her creosote for a few weeks and entirely recovered.

Case II.—In December, 1892, I was called to see a little girl aged eight. She had a follicular tonsillitis and a slight inflammation of the mucous membrane of the large bronchial tubes. There seemed to be nothing unusual in the case, and I looked for a speedy recovery. She had had bronchitis affecting the larger bronchi every winter all her life. The bronchial inflammation seemed to be simply an exacerbation of her old trouble. She improved slightly, but her pulse continued rapid and the temperature failed to decrease as I expected. I sought an explanation. I re-examined the chest, but failed to pay proper attention to the apices, and discovered nothing new.

The possibility of a malarial element suggested the administration of quinine, and moderate doses were given. She did not improve at all. The quinine was increased to an equivalent of thirty grains daily for an adult, and continued for four days. There was no change for the better. Her chest was again examined, and this time the apices received proper attention. At the left apex transference of heart-sounds was detected, also an exaggeration of the normal rough breathing found in childhood. She was given one-half-drop dose of creosote every two hours, and within two days her improvement was marked. After continuing this treatment for a few weeks she recovered.

Case III.—In January, 1893, I was called to see a boy aged eight, who seemed to have a slight catarrhal laryngitis only. Tincture of aconite and small doses of morphine, with alternate doses of calomel, were prescribed. He was subject to such colds, and as I had seen him before in such an attack I considered the case of little gravity. After five days his mother brought him to my office. His temperature was 100° F., and his pulse was slightly accelerated. No special importance was attached to the rise of temperature, but he was given two grains of quinine four times a day. After one week his mother brought him back and said he had a poor appetite, was very much depressed mornings, and complained of feeling tired. His chest was examined after finding his temperature slightly elevated and pulse more rapid than normal. His right apex was suspicious, but the signs were not well marked enough to enable me to give a positive opinion. Small doses of creosote were given and the quinine was discontinued. He rapidly improved under the change. After one week the continuance of the treatment was advised, but he stopped his medicine after he had taken it two weeks. For a month he disappeared. Then his mother brought him back again. His temperature was 102° F. and his pulse was 120. The catarrh at his right apex was now well marked. He was put back upon his creosote. For a week his temperature remained about 102° F. at night, and his pulse continued rapid. His improvement this time was much slower than six weeks before. After a week he began to improve. He now continued his treatment more nearly as I advised, and after a few weeks his recovery was complete.

Etiology.—I know nothing as to the causation of this disease in children. Station in life seems to have little influence. Season of year also seems to have nothing to do with its occurrence. Parents, almost without exception, attribute the child's condition as being due to an acute cold: whether the catarrhal condition at the apex owes its origin to the acute cold, or whether a catarrhal condition at the apex existed before the onset of the acute cold, I cannot say. The symptoms in children differ so much from those in an adult, that it is impossible to fix a definite limit to the onset of the disease.

The symptoms in children are very much less marked than in adults. They either suffer much less or are observed much less closely. The objective symptoms in a child with apex catarrh may be almost altogether wanting. There is usually no anæmia. The gastro-intestinal disturbance so marked in adults, usually only shows itself in a slightly coated tongue, and no complaint of stomach is made. I have never observed any irritation of the genito-urinary mucous membrane in a child. If a child suffering from an apex catarrh has no pharyngitis or laryngitis, no sputa can be obtained. Consequently I have made no microscopical examination of the sputa in these cases. The subjective symptoms are more marked in children than in adults. Frontal headache is common. Often the parents notice that the child is restless and does not play as much as usual. A small proportion of cases are pale and depressed in the mornings. They do not seem to suffer more one day than another. The appetite is usually slightly impaired. The chest examination reveals on inspection usually nothing. Congestion of the superficial veins may be observed, in well marked cases slight flattening.

On percussion nothing is detected, neither localized tenderness nor elevation in pitch.

On auscultation, transference of heart-sounds is the earliest sign as well as the latest. Often we can detect only transference of heart-sounds. In well-marked cases an exaggeration of the normal rough breathing in children, as well as cog-wheeled breathing, occur. Auscultation is ordinarily the only method of any value in the diagnosis of apex catarrh in children. In slight cases it is extremely difficult to decide, and I believe it only possible after long training. I see many cases in which a positive opinion cannot be given.

The observation of the temperature is much more important in children than in adults. The temperature in adults with an apex catarrh may be normal even at night. I have not observed this in children. If it be possible, such a case has not as yet appeared. If the temperature is normal I consider a chest examination unnecessary. If there is a slight rise of temperature the chest ought always to be examined, for I do not know how an apex catarrh in a child can be otherwise diagnosticated from an ordinary bilious attack. The pulse also is always rapid in children. The course of the disease is much shorter than is the rule in adults. A case that feels the need of continuing treatment more than six weeks is the exception. Parents almost uniformly insist upon knowing whether the child needs to continue its treatment more than a week longer after the child feels as well as ever.

Cases of apex catarrh in children always recover in my experience; why they should invariably recover I cannot say. A small proportion of such conditions in adults do not recover. I have yet, however, to see a case in a child that became a tuberculosis.

The treatment is the same as for an apex catarrh in an adult. As a rule, however, one needs to give little attention to the gastro-intestinal tract. Children respond to treatment more promptly than adults. If children will take creosote they seem to do as well as they do when benzoal is given. Benzoal is a pleasant remedy.

In this respect only it has seemed to me to be superior to creosote. I have not found that the other superior qualities claimed for benzoal have been realized. Small doses of creosote or benzoal are all that is necessary. One or two drops of creosote four times a day is enough for children under ten years of age. Benzoal need not often be given in larger doses than one or two grains four times a day. I sometimes give one grain of benzoal every two hours if the case seems at all urgent. While I believe some form of beechwood creosote to be the best remedy in apex catarrh in children, I realize the fact that they do well on other remedies. I do not know but that the local lesion recovers as soon when general tonics are given, but I do know that the subjective symptoms are much more promptly relieved if creosote is given. It certainly is a satisfaction to be able to say that "this child will be better within four days, and probably you will notice a change within twenty-four hours." If creosote is the remedy you can make such a statement and not run any risk. If some other tonic is given I would not know what to promise as to any immediate effect.

323 Hickox Building.

OPERATION FOR THE CORRECTION OF DEFORMITY OF THE WRIST CAUSED BY SHORTENING OF THE RADIUS AFTER FRACTURE.

By E. S. GOODHUE, M.D.,

RIVERSIDE, CAL.

April 28, 1892, Mrs. M——, aged forty-three, American, housewife, of good family history, consulted Dr. C. J. Gill for ununited fracture of the right radius at junction of the upper with the middle third—ancient, four months.

The arm presented the usual deformity of a closed, uncomplicated fracture of the radius above the insertion of the pronator teres muscle, with shortening, preternatural mobility, deviation of the hand toward the radial side, and showing marked displacement of the upper end of the lower fragment toward the ulna. Crepitus distinct, with power of pronation and supination gone. An attempt was made at once by Dr. Gill to convert the ancient fracture into a recent one by more or less forcible bending and rotation, so that the newly freshened ends might be brought into apposition and result in consolidation, after which the arm was placed in straight wooden splints and treated as a recent fracture. This was followed by the usual hygienic measures. But the bones would not unite, and after repeated attempts to encourage consolidation it was decided to do a more radical operation.

Accordingly, on August 30, 1892, Dr. Gill operated, making an open fracture, Dr. Rutherford and myself assisting, and in a longitudinal incision cut down to the separated extremities, which were turned out and sawed off. A small fragment of bone, which resembled a part of a comminution, was removed from the end, but only enough was taken away to secure a broad, fresh surface, without destroying too much periosteum. The bones were found somewhat diminished in calibre at their broken ends, presenting a "whittled-off" appearance, as the result of absorption; the lower end of the upper fragment being to the ulnar side. After resection of the bones they were brought into perfect apposition and fastened together by silver wire, the ends of the wire extending beyond the external wound; the forearm was then put up in straight wooden splints, such as are usually employed for fracture of the radius below the insertion of the round pronator

In three weeks more absolute bony union had not taken place, and slight crepitus was discernible. The flesh wound had healed by first intention, excepting at the point irritated by contact with the wire. On the removal of this irritant, and after slight manipulation of the fragments, the splints were removed. Union was finally secured, but at the expense of a perfect arm. There was a pronated inclination of the wrist toward the radial side, with shortening there, and a decided increase in the circumference of the wrist, the lower end of the ulna reaching three-quarters of an inch beyond the radius, its styloid process lying upon and beyond the cuneiform bone. The inter-articular fibro cartilage was evidently stretched, and considerable pain and soreness were referred by the patient to the wrist, but she felt none at the seat of fracture. The angular deformity which resulted was exceedingly ungainly, and at the same time interfered with the usefulness of the arm. The accompanying illustration, taken from a photograph, is a correct representation of the arm as it was a day before the second operation, done July 6, 1893.

October 20, 1892, the straight splints were taken off, and a right-angled wooden splint fitted so as to thoroughly immobilize the arm, and, if possible, remedy the defect of deviation, but without success.

Dr. Gill now decided upon performing a radical operation to correct the defect if possible—an operation no less than the removal of a portion of the ulna. Without precedent to go by, the doctor still believed that by this means the wrist could be straightened and the protuberance removed. Records of cases were looked into, and orthopedic annals scanned, but no similar operation was found described in any of the works consulted. Dr. S. C. Lane, of San Francisco, who was written to concerning the proposed operation, answered as follows: "In your patient the attempt to shorten the ulna would be a justifiable procedure, and probably bring some improvement. Your case verifies what every surgeon learns to his regret, that a Colles's (?) fracture in a woman who has passed the meridian of life is a troublesome matter,

and do what one can, the result is never very satisfactory."

On Thursday, July 6, 1893, Dr. Gill cut down upon the ulna at about the junction of the middle with the lower third, just above the attachment of the pronator quadratus, removing five-eighths of an inch of bone, bringing the ends into perfect apposition and closing the external wound. As soon as the fragment of bone was sawed off the angularity of the wrist became less apparent, and the bulging styloid process gradually took its accustomed place, making, after the lapse of a few days, a normal-looking wrist.

A pistol shaped wooden splint was then carefully adjusted, the forced deviation being to the ulnar side, in

order to keep the two ends of the newly separated bone in apposition, and to correct the old deviation toward the radial side. Union was rather slow, although the wound healed by first intention, and after six weeks of rest some crepitus could still be detected. The arm was now put up in a silicate of sodium splint, where it remained until within the last few weeks. At present writing union seems perfect. The arm is three-quarters of an inch shorter than the other, presents a normal appearance, and can be freely used. The hand is pronated or supinated at will, and has an amount of lateral motion, while the deformity of the wrist is absolutely corrected. There is no pain or soreness. A photograph of the arm was taken October 7th, and shows the arm as it is to day, three months after the operation.

The cause of the delayed union of the radius and ulna is not so easily explained, as the patient was not old nor in poor health at the time of the operations. After resection of the radius union may have been delayed by the wire, which kept an open wound. When the wire was removed, union came about. In such a case it is a question whether chromicized catgut would not have been better than the wire. In the delayed union of the ulna it may be that the strict antisepsis secured during the operation prevented the necessary amount of irritation and so defeated union, which finally occurred after repeated manipulation.

To the pluck and indomitable will and perseverance of the patient is due, in a great measure, the ultimate success of the operation, for the results are eminently satisfactory, and the patient is living to testify with enthusiasm as to the success and practicability of this new operative procedure.

THE REVIVAL OF SYMPHYSEOTOMY.

By CHARLES WILLIAM STROBELL, M.D.,

RUTLAND, VT.

It would seem that we have at last means to abolish the horrible operation of embryotomy—at least in the vast majority of cases. I say "at last" advisedly, since it is not a new operation, but one proposed and performed by Jean de la Courvée in 1644, then allowed to lapse into oblivion until 1768, when it was resurrected by Sigualt, in France, but not actually performed by him until 1777, when, after a short season of doubtful success, the operation was again abandoned, on account of the fatality attending it, which fatality we now know to have been due to ignorance of the laws of asepsis in surgery.

The revival of symphyseotomy (or pubiotomy, as it is perhaps more properly termed) by Morrisani, of Naples, in 1866, in the land of its birth, was the natural outcome of the aseptic theory, for these worthy descendants of men illustrious in the annals of Italian medicine were not slow to perceive that asepsis lay at the root of all failures charged to the operation in 1644 and 1777, causing its discontinuance. They boldly acted upon that conviction, with what magnificent results we are all perfectly familiar. Operators of other countries were prompt to follow in the wake of such success, until now reports of cases awaken but slight interest, as it is almost a foregone conclusion that the case recovers, and that the "mother and child are doing well." We are, consequently, more interested, when about to read such reports, to learn about the union of the symphyses, than to learn whether the lives were saved.

The knowledge of the revival of symphyseotomy, and its brilliant results, was imparted to the profession in America in 1892, by Dr. Harris, of Philadelphia, who had collected reports of forty-four cases, all by foreign operators, with only one recorded maternal fatality, and three children. Our American surgeons were not slow to follow such a lead, with results fully equal to those of their foreign confrères.

In a community such as ours, there occasionally occurs a case in which the ghastly operation of embryotomy stares us in the face, on account of a justo minor, or a simply flattened pelvis, whose diameters are such as to render it impossible to extract a living child; the usual alternative, Cæsarean section, being, as usual, declined, which is in perfect accord with the law of self-preservation. It is in these cases, and in those of abnormal cranial development, sure to lead to fatal fœtal compression, that symphyseotomy steps in, and, without materially increasing the risk to the mother, rescues the child from a needless death.

Symphyseotomy is not a panacea for all abnormal conditions of the puerperal pelvis. It has its peculiar sphere, as have also embryotomy, Cæsarean section, pubio-ischiotomy, Porro's operation, and their various modifications, and cannot in every instance take the place of any one of them. Its range of utility is rapidly being determined, and its technique perfected. It is said to be a simple operation in the hands of skilful operators.

In the determination of the indication for symphyseotomy, after exclusion of such manifestly inoperable

cases as cancer of the cervix, fibroid tumors, rigidity of the os uteri, anchylosis of one or both sacro-iliac synchondroses, and that form of pelvic deformity wherein the symphyses and rami of the pubes are unusually deep and thick, or in the Negéle or the Roberts pelvis; pelvimetry is an absolute necessity, except in those very rare cases where the general deformity is sufficiently obvious. Manual pelvimetry alone will not do; the examining finger should give the warning; the pelvimeter must solve the problem.

We come now to the consideration of the limits, maximum and minimum, of the diameters of pelves requiring pubiotomy.

We find that there is some diversity of agreement among those whose experience, though as yet so limited, we must look to for light on this point. I said "diversity of agreement"—it certainly is a fact that thus far, among American operators at least, I have found four observers advocating different minimum conjugatæ veræ. Murray, of New York, two and three-eighths inches; Jewett, of Brooklyn, two and one-half inches; Edgar, of New York, two and five eighths inches; Stanton, of New York, two and three quarter inches. The variation in question being three-eighths of an inch. Concerning the maximum, this may be even from three and one-half to four inches, if craniotomy had to be performed on all the patients' previous labors, indicating some peculiar deformity. But these again are the exceptional cases.

Dr. Jewett, in the medical and surgical reports for April, says on this point: "Two and one-half inches conjugatæ veræ is the limit. The maximum will, no doubt, in the future encroach to some extent upon the present field of forceps and version." The pelvimeter of Baudelocque, which is perhaps representative of its class, will give approximately the antero-posterior or conjugate diameter. By placing one point of the instrument over the lumbo-sacral articulation, opposite the sacral promontory, the other resting on the anterior middle portion of the pubes, the reading will indicate the approximate conjugatæ diameter. The transverse being obtained by placing the points of the pelvimeter upon the anterior superior spinous processes of the ilia, which measure nine and a half inches, while between the widest parts of the iliac crests the result should be ten and a half inches. Of course there is quite a variety of pelvimeters, but we will not consume time with a description of them. Of manual methods, Ramsbotham's method is the simplest and best.

This much for pelvimetry. Now, as regards the determination of the diameters of the fœtal crania, which is considered of such great importance, as it certainly is, Murray says, on this point, in the *American Journal of Obstetrics*: "The determination of the size of the child's head is important as a factor of all elective obstetrical operations if a living child is to be obtained." I agree with Dr. Murray as to the advisability of such a determination, but have grave doubts as to its universal applicability. It is of the greater moment, in my judgment, to ascertain the degree of mobility of the cranial bones, which, cartilage-like, in the majority of cases, adapt themselves wonderfully at times, during the moulding process, to contracted conditions, even in some cases overlapping. Of course, if the head is large and cranial ossification well advanced, we need not expect much from this source. I consider the determination of the cranial diameters, in utero, impracticable with our present means of obtaining them. It is well to bear in mind the rule laid down by one author, whose name has escaped me, which is as follows: "Cranial ossification of the fœtus, and the compressibility of the head, diminishes progressively with the age of the mother. This fact should be given due weight in the solution of all obstetrical problems."

So much for the indications, and their determination. Now let us examine into the effects of the division of the symphyses, as regards gain of space. I will have to quote authors who have made this a study, both upon the living and upon the cadaver. The one important point noted in this connection is, that the amount of space gained, or, the diameter after symphyseotomy, is greater in practice than one would expect from theoretical considerations, or, from experiments upon the cadaver. Herzel, of Dresden, whom I quote at some length, in an article in the May number of the *Journal of Obstetrics*, says: "Under the influence of pregnancy, the pelvic joints partake of the general development of the generative organs. Their ligaments and cartilages become swollen and softened, and the synovial membrane, existing between the articulating surfaces, is greatly augmented in size."

"In conformity with Morrisani's writings are the results of an investigation of 25 pelves; in brief as follows: In 13 of these, laceration of the sacro-iliac ligaments resulted, when the distance between the pubic bones amounted to 6 ctm. (*i.e.*, two and one-fifth inches), or less. Ten of these pelves were from women above sixty years of age. They were all much emaciated, and suffered from chronic disease. In a second group of cases the sacro-iliac joints separated between 6 to 8 ctm. (*i.e.*, two and one-half to three inches). These bodies were from younger and better nourished individuals. And in 4 puerperal pelves, the articulation could be separated from 8 to 9 ctm. (*i.e.*, three to three and two-fifths inches), before a luxation of the sacro-iliac synchondroses was observed. But even the experiments upon puerperal pelves give no proper conception of the ease with which the pubic bones separate in the actual operation upon the living woman. If we divide the symphyses in the corpse, the bones separate about 1 ctm., while in the living woman a spontaneous separation of about 3 ctm. takes place. To obtain a greater separation than 1 ctm. requires, in the dead woman, a certain degree of force, but in the living woman counter-pressure upon the trochanters is necessary to prevent too great a separation of the bones."

Decidedly interesting is the examination of 60 female pelves, as regards the exact location of the symphyses. In only 8 cases was the joint in exactly the median line. In 40 it was to the left, in 12 to the right, of a line drawn through the centre of the promontory. It matters little which diameter is at fault, whether transverse or other deformities, the pelvic diameter increases in all directions about two inches, but varies with the age of the patient.

According to the conclusions of Boucicourt also, the dimensions of the pelvis are increased by simply cutting through the symphysis. He further says, "When the legs are adducted, yet without forcing the crests of the iliac bones apart, and without any incisions having been made in the connective tissue, the aponeuroses, or the surrounding ligament, the distance between the ossa pubes can, without any tearing of the soft parts, or any dislocation of the sacro-iliac articulation, be increased to 4 ctm. (one and three-fifths to two inches) up to 5, yea even up to 8 ctm. (two and two-fifths, three, three and one-fifth inches), according to some obstetricians, especially if the operation was made immediately after death, and on a young and weak person."

It is plain, therefore, that experiments upon the pelves of women who have died either shortly before or after labor, alone can give a correct estimate, as to how much room there may be gained by this operation. As to the amount of room gained by symphyseotomy, it is the general verdict that all diameters are enlarged about two inches. Separation of 1 ctm. (two-fifths of an inch) increases the conjugate diameter one-twelfth of an inch. Pubic bones can safely be separated three inches, which implies that we can elongate conjugate of brim three-fourths of an inch, or one-fourth of an inch enlargement of conjugate of brim to every one inch of separation.

The proper time to perform the operation is at the end of the first stage, when the os is fully dilated, after which, unless contra-indicated, the woman may be left to nature.

In preparing to perform symphyseotomy, it should be borne in mind that the interarticular cartilage is not always in the median line, and that exostosis, or anchylosis, from inflammatory processes, may exist, necessitating the employment of the chain-saw, which should be always at hand. The use of the saw in pubiotomy has thus far had a somewhat bad record, otherwise it would be the safest of instruments for the division of the joint, since it insures greater safety to soft parts. Also, though not a bloody operation, still the rule should be to have at hand a supply of hæmostatic forceps. The most vascular tissue to be divided is the subpubic ligament. A good, strong, blunt-pointed bistoury, with stiff handle, is, in my judgment, the instrument to be chosen, rather than the Galbiati falcetta, or the new Harris knife, which is constructed on much the same plan.

The manner of cutting also deserves a word, *i.e.*, whether it is best to cut from above downward or from below upward.

Herzel, in his Dresden clinic, prefers the former method for the purpose of preserving the ligamentum arcuatum, which it is deemed desirable to preserve intact. He finds that the amount of separation is one inch without the division of the ligament, which is increased to two inches when it is divided.

The desirability of cutting from below upward (if it is desired to make a complete section) is in the fact that it is better protection against injury to the urethra and vessels. Division of the symphysis is painless, and repair speedy; from two to four weeks the rule.

Rules for Operating.—1. The operation should always be done under an anæsthetic and in the lithotomy position.

2. The woman must be free from infection.

3. The pelvis must not be anchylosed, or have an extreme oblique contraction.

4. The fœtal heart-sounds must be good.

5. Desirable conditions are that the woman be a multipara, and that the tissues are sufficiently prepared.

The technique of the operation is as follows, still quoting from Wehle:

1. Emptying of the bladder; thorough disinfection of the abdominal walls, and the external and internal genitals.

2. The operator stands between the extended legs, which are supported by one assistant on either side. These assistants place one hand under the knee, and with the other hand make counter-pressure against the sides of the pelvis.

3. Incision down to the symphysis.

4. Division of the muscularis pyramidalis, and detachment from the symphysis of the prevesical tissues.

5. The index-finger is placed behind the joint, which is then divided with a curved probe-pointed bistoury, from above and behind, to below forward. In looking for the symphysis, it should be remembered that its situation, in the median line, is the exception. The ligamentum arcuatum should, if possible, not be divided.

6. The fœtal head is pressed into the pelvis, and delivery accomplished. While the head passes through the pelvis, the legs should be extended, and the assistants should make counter-pressure against the trochanters.

7. Arrest of hemorrhage.

8. Suturing of the wound by three or four strong silk ligatures. The sutures should be passed through the skin, and made to include the anterior surface of the symphysis.

9. The pelvis is immobilized by a strong canvas belt buckled in front. The use of silver wire in suturing the symphysis together, to insure union, as recently advocated, seems to me, in view of the almost invariable and speedy union without it, to be superfluous, except in cases, perhaps, where the saw has been used in anchylosis or similar conditions. Here the condition is similar to a compound fracture, and silver-wire sutures might be desirable.

Pain in the knee, when obscure, should suggest examination of the hip.

PHARYNGO-MYCOSIS.

By HOMER M. THOMAS, A.M., M.D.,

CHICAGO, ILL.

The term pharyngo-mycosis signifies a fungoid condition of the pharynx. It is a parasitic affection of the mucous membrane of the mouth, and manifests itself in white patches of varying sizes. These are found to contain epithelial cells and parasitic forms of a vegetable nature, the distinctive ones being called leptothrix threads. The tonsillar crypts of healthy persons are sometimes more or less plugged by these vegetable masses, but it is only when the plugs are large enough to project slightly over the surface that they come under observation. Mycosis leptothrix occurs in two forms, diffused and circumscribed. In the diffuse form the entire tongue is coated with a shiny, milk-white mass, which is frequently of sufficient density to obscure from view the villiform papillæ. Movement of the tongue and sense of taste are not lost, and there is no interference with the general health. In the circumscribed form white, glistening points appear, resembling those seen in follicular tonsillitis, except that the mucous membrane about them preserves its normal pink hue. The tonsils, pharyngeal walls, and base of the tongue are apt to be invaded. White or yellowish-gray spots, usually hard, are arranged in groups or singly, and form little excrescences on the normal mucous membrane. They adhere firmly to the surrounding parts, and reappear if removed by forceps. The leptothrix buccalis is found in carious teeth, and in the accumulations known as tartar; a microscopical examination of the secretions of the mouth will almost always find them. You should look for these collections in the lymphatic tissue at the base of the tongue, in the faucial tonsils, and in the adenoid tissue of the vault of the pharynx.

Some of these white spots resemble a mushroom in shape, others are like pointed cones. The mass seems to be in layers, the outer one being easily smoothed off, while there is a deeper and harder substratum in the shape of little plaques. These little excrescences have their attachments on the surface and in the openings and depressions of the tonsils, or on the palatine arch, often on the posterior pharyngeal wall, the side of the pharyngeal wall being sometimes involved. When occurring on the tongue, they have their attachments in the region of the large papillæ. Sometimes this mass is cheesy and easily removed; sometimes tough and stringy, running deep into the follicles, being very tenacious and difficult to remove. Dr. Fraenkel, of Berlin, first pointed out, in 1873, an abundance of leptothrix threads in these products, and since then this has been noted by many observers.

However numerous these small, white projections may be, each spot is isolated and they never form a continuous mass. After the tonsil the glandular subtissue at the base of the tongue is most frequently affected; and the growth here may be extensive, the masses attaining the size of a pea. In some cases mycosis involves all parts of the pharynx.

Pathology.—The gross appearance of the lesion is that of discrete white spots, which may be connected here and there by scanty threadlike filaments. The mucous membrane covering the tonsil is the part most frequently invaded. In so-called fetid bronchitis the leptothrix threads have been found in the tracheal mucous membrane, in the characteristic fungoid plugs; they have also been found in the sputa of pulmonary gangrene. In fourteen cases reported by Heyring, the affection was confined to the tonsils in seven, in the remainder the base of the tongue was also affected. Six were men and eight were women. The ages varied from twelve to sixty-two, the preponderance being between twenty-eight and thirty-five.

The characteristic feature of the circumscribed form is, that although it quickly redevelops, often in twenty-four hours, in the same spot from which it has been re-

moved by instrumentation, its extension to other points is comparatively slow; that is, new foci of the disease develop sluggishly, but when once established their tenacity of life is very great and radical methods are required to destroy them.

From diphtheria this disease may be differentiated by the persistent discrete arrangement of the exudate; the general absence of surrounding inflammation, and the masses being much harder than pseudo membrane. The tongue may also be involved, which is rarely the case in diphtheria. The absence of the Klebs-Loeffler bacillus would be convincing. Mycosis of the pharynx may be confounded with cheesy masses in the crypts of the tonsil and follicular disease of the throat, but the ease with which the cheesy masses may be expressed from the crypts of the tonsil is in striking contrast to the fixation of the mycotic masses. The constant presence of inflammation in follicular disease, and an entire absence of inflammation in mycosis are distinctive of the two diseases. The exudation of follicular tonsillitis is a yellowish-white; it frequently becomes confluent, and upon the application of the salt of iron it is readily disintegrated and may be largely removed.

Microscopical Appearance.—Microscopical examination shows a general mass of epithelial cells surrounded by an irregular collection of fungoid spores arranged in linklike processes, their ends being rounded or club-shaped. They vary in length and some curl up at the ends into hairlike filaments, others are like rods, colorless, with sharp dark borders, the centres seeming to be full of granular matter. Besides these spores there are round or oval highly reproductive bodies, with dark borders, arranged in colonies or placed separately between the branch spores. Staining with methyl blue brings out colored and uncolored portions on the stem spores. Jacobson succeeded in making a pure culture of these organisms. Leptothrix has the peculiarity of dissolving the chalk deposits of the salivary ducts and glands. Miller describes the microscopical appearance as a dirty yellowish deposit, varying in size from the head of a pin to a pea, consisting of numerous bacterial forms and extending deep into the lacunæ of the tonsil.

Etiology.—The etiology of pharyngo-mycosis is very uncertain. Mouth-breathing has been suggested as the cause. Tonsillar hypertrophy is a predisposing cause. It has been noticed as a sequel to rheumatic amygdalitis. Some observers have mentioned damp localities as favorable to the growth of this fungus. Catarrhal inflammation is a predisposing cause. It is more frequent in females than in males. Tobacco-smoking is thought by some to have a preventive action. The resemblance of the bacilli to several forms found in water, especially the water from marshes, has suggested the possibility of such a source of infection. In several instances it has been observed to follow or excite affections of the pharynx. It occurs most frequently in women and children who suffer from enlarged tonsils and are disposed to chronic pharyngitis. Some writers claim that a condition of malnutrition, with an impaired state of health, may be considered as a provoking cause; others claim a positive relation between disturbances of digestion and mycosis. W. C. Glasgow believes that some peculiar condition of the mucous membrane is a necessary factor in the development of mycosis, and that it only exists when the membrane presents a soil which favors its growth and development. The disease is not directly transmissible, and is not contagious.

Symptoms.—The subjective symptoms of pharyngo-mycosis are variable; sometimes there exists a sensation of tickling and dryness in the throat, confined to the pharynx. Again, there may be a feeling as if the throat had a band drawn around it giving rise to a slight choking or feeling of pressure; slight pain on swallowing, the feeling of the presence of a foreign body, attended with an irritation which causes a desire to clear the throat and to cough. In some cases these symptoms are greatly exaggerated, with depression, considerable fever, and loss of appetite. The disease may exist without any symptoms being apparent to the patient, if not a vocalist. Mycosis in the throat of a vocalist produces great dryness and irritability of the fauces after a short vocal use of the throat. The voice is rather lowered in tone and inclined to be husky.

The objective symptoms are spots upon the pharyngeal wall, and often the circumvallate papillæ of the tongue are invaded. The color of the spots may be white, cream-colored, or yellow.

Treatment.—Dr. Kitchen has suggested hyposulphate of sodium as a means of treatment, especially if allowed to soak in well and applied repeatedly with a swab. Peroxide of hydrogen has also been recommended. Semon claims to have cured a case with chlorate of potash gargle and troches of tannic acid; Seiffert, with iodine and a gargle of borax, but doubt has been expressed as to the correctness of the diagnosis. Alum and sulphur have been found useless; silver nitrate resulted well in two cases that were especially tolerant to its use, but a relapse occurred later. Jacobson recommends a bichloride gargle, 1 to 2,000. Toeplitz found ferric acid useless, and others have had a similar experience with other iron salts. Carbolic acid has produced negative results. All of these agents have proved unreliable, and nearly all of them useless; fused chromic acid has given better results. At best superficial applications like gargles can only affect the top of the growth, while its base remains firmly bedded in the tonsillar crypt, and the forcible rubbing on of solutions may abraid the epithelium and so permit the spread of the disease. Glasgon advocates the destruction of the organism with the cautery, or forcible extraction with the forceps where the growth has assumed a horny, threadlike character. In some cases he advises scraping of the spots with a sharp curette and applying trichloracetic or chromic acid freely to the surface. He has found the application of boracic acid in saturated solution of value in preventing the spread of the disease. The treatment is always tedious, with a tendency to return until all evidences of the disease have been eradicated. The most successful and certain treatment is the use of the thermo- or galvano-cautery. The bacillus frequently penetrates the tissues to the depth of one or two millimetres, hence the cauterization must be deep in order to destroy the germ. The bacillus thrives best in an acid medium. If the negative pole is used for cauterization, with a large positive electrode, there is a deeper action upon the tonsil and the growth is surrounded by alkaline fluids. The point of the galvano-cautery should be thrust into the root of the growth.

I am under obligations to Dr. F. D. Owsley, of this city, for translations from the German of Schech. I am also indebted to the writings of Drs. Fraenkel, Rice, Vanderpoel, Newcomb, Hemenway, Glasgon, and others.

The following case of pharyngo mycosis was kindly referred to me by Dr. Fraenkel, of Berlin:

The history of the case as given by the patient, Mrs. C. B——, is, that during August, 1892, she suffered from a slight irritation of the pharynx. There were white spots on the tonsils, which disappeared after a few days but returned within a couple of weeks. The physicians consulted called the trouble a mushroom growth and said it would require two or three treatments a week for some three months to effect a cure. The treatment consisted of a forcible removal of the exudate by means of forceps. This method of treatment was attended with severe pain and proved unsatisfactory. The patient, becoming discouraged, consulted Dr. Fraenkel, of the Berlin University, in November. At that time he found spots covering the tonsils and extending to the root of the tongue. His treatment consisted of swabbing the throat two or three times a week with a five per cent. solution of carbolic acid, and he recommended that the throat be gargled two or three times a day with pure brandy. Under this treatment the throat seemed to grow somewhat better, but still the disease was not wholly eradicated.

Having been called to this city, Mrs. B—— came un-

der my care January 4, 1893, at which time the pharyngo-mycotic deposit was very extensive upon the posterior pillars of the fauces and invaded the root of the tongue, almost completely covering it, and there were extensive deposits upon the tonsillar substance.

After having confirmed the diagnosis as made by Dr. Fraenkel, through microscopic examination of the deposit, I advised treatment, to consist of thorough applications of the galvano-cautery. The electrode selected was one made for me in Vienna, and consisted of a very fine elongated platinum point, which enabled me to introduce it directly into each one of the crypts of the tonsil affected by the disease, and also to eradicate the punctated growths at the base of the tongue. At first only three or four punctures were made at each treatment, the treatments occurring three times a week. As the patient grew more tolerant of the irritation following the use of the galvano cautery the number of punctures per treatment were increased, until I frequently applied the cautery to eight or ten of the mycotic masses at each treatment. The effect secured has been satisfactory to the extent that the disease has not reappeared in any of the foci cauterized.

My experience in these cases leads me to believe that the galvano cautery treatment for pharyngo-mycosis is the most nearly a specific in the management of this disease of anything we have.

Clinical Department.

ATROPIA-POISONING FROM EATING TURKEY.

By H. H. SEELYE, M.D.,

Amherst, Mass.

I had what I believe to be a unique experience in the poisoning line last week. In a young ladies' boarding-school in this place fifteen people sat down to their Thanksgiving dinner. When they had been at the table about three quarters of an hour they all began to notice an uncomfortable dryness of the throat, mouth, and lips. Then some noticed a sense of dizziness which was more marked when they left the table and attempted to walk. Vision was so affected in two or three that they were unable to read ordinary print, the lines being blurred. These proved to be girls with a high degree of hypermetropia, in whom accommodation was paralyzed. This led them to look into one another's eyes, and they noticed that, in all, the pupils were markedly dilated. A few had flushed faces and some headache.

I was summoned to visit them about four hours after they had finished eating. Their experiences at the table had not prevented their eating the usual large-sized Thanksgiving dinner. The symptoms described above still persisted, the dryness of the throat and dilated pupils being universal. On inquiry I found that turkey, of which there were two, and water were the only articles on the table of which all had partaken. Some had eaten no dressing and some no gravy. I examined and drank some of the water, which appeared perfectly natural. This led to suspicions of the turkey, and I asked for some pieces to take home to examine. These I received and departed.

That same evening I cut off about an ounce of brown meat, an ounce of the breast, and a small piece of the skin and made a hash of them, which I steeped in a little warm water for about an hour. Then I filtered off some of the liquid and placed a drop in my left eye. I added other drops at intervals of a few minutes. In half an hour I noticed a slight enlargement of the left pupil, and in an hour it was dilated to double the size of the right one. The difference was slight on looking at a bright light, but very marked when directing the eyes toward a dark object. This dilatation continued till midnight, when I retired. On examining my eyes in the morning, I found both pupils alike. When I called that forenoon at the school to report the result, I found most of the dryness of the throats gone and the pupils of natural size, but one or two could not see to read clearly yet.

How to account for the peculiar effects of eating those two turkeys is a puzzle. The butcher who supplied them was not sure whether they were raised in Michigan, Vermont, or Massachusetts. Other turkeys probably came from the same place, but I have not heard of any similar effects being produced anywhere in town. No atropia or other suspicious material had been lying about the kitchen or used by the cook. It seems most probable that the turkeys had fed on some of the leaves or seeds of some plant of the mydriatic group growing on the farm where they were raised. It is a proven fact that birds are not at all affected by atropia in doses that would severely poison other animals. Though the proof is unsatisfactory, it seems that the flesh of these turkeys must have become impregnated with either belladonna, stramonium, or hyoscyamus ingested with their food, in such quantities as to produce physiological effects in thirty or forty people, if they had eaten all of the flesh of these birds. What was left of the turkeys was burned.

A BIFID UTERUS WITH TWINS.

By E. H. SMITH, M.D.,

Santa Clara, Cal.

On the morning of August 24, 1893, I was called to see Mrs. A. T. H——, then in labor. On my way to the house I was told by Mr. H——, "We expect twins at our house, and I will tell you why! My wife's stomach is unusually large. Besides that, she has suffered such awful inconvenience while carrying this child, or these children. She can do nothing at all!" At 10 A.M. I arrived at the house. Upon examination I found the os about two-thirds dilated, the vertex presenting. Turning my attention to the abdomen I found it very large and pendulous. The recti muscles were separated and thin as the integument over them. The uterus, on inspection, seemed to lie to the right of the median line. By palpation two children could be mapped out. The one presenting at the os lay with the back to the left, and breech just below and to the left of the umbilicus. The fœtal heart-sounds could be heard at about the centre of a triangle bounded by lines drawn from the umbilicus to the "symphysis;" umbilicus to the anterior, superior spinous process, and from the latter point to the symphysis. The second fœtus lay with the head above and to the left of the umbilicus; back to the right and breech lying against the internal surface of the ilium. The fœtal heart could be heard on the right side, and several inches to the right of the umbilicus. For a time the pains were not expulsive in character. About 10.30 A.M. they became strong and good. The "waters broke," and at 10.45 the child was born, the shoulders rotating without any apparent cessation of the pain, so that the whole child was expelled at a single pain. (The perineum had been deeply torn at a former delivery and never repaired.) Putting two ligatures on the cord I liberated the child, a well formed girl, weighing five and one-half pounds. The pains ceased for a time, and then began in a weak, unsatisfactory manner. The second fœtus remained in an unchanged position. I tried by external manipulation to bring it to engage in the pelvis, but with no effect. As the patient's general condition was good, and no hemorrhage, I did not attempt to hurry matters. The pains ceased and the patient had a nap. At 1.20 P.M. the pains began lightly, but with growing intensity. I noticed that every pain forced the breech of the child against the ilium instead of toward the pelvic outlet. About 2.30 P.M. the patient began to flow somewhat. I made a careful examination, but could feel no part of the second fœtus presenting, and no sign of the descent of a placenta. Carefully recleansing my hands I introduced my left hand into the uterus. Passing my fingers along the right side of the lower uterine segment I came abruptly to a hole, which felt much like

an os uteri just beginning to dilate. I could, with some difficulty, pass two fingers through it. Between the thumb and fingers I could grasp an intervening wall or septum between the two portions of a bifid uterus. Sweeping my fingers around to the right side of this second compartment, the uterine wall was as thin, apparently, as a gut. I could make out a bag of waters, foot, and breech. I withdrew my fingers and passed them to the fundus of the left compartment, where lay the placenta to the babe already born. I withdrew my hand, and by two pains immediately following the placenta above mentioned came away. The question now arose, Can this second child be brought through that secondary os without danger of rupture? The walls overlying the breech were very thin, and the whole right compartment very tightly stretched over the fœtus, indicating that it was a rudimentary portion of the uterus. I called in Dr. H. J. B. Wright, of San José. After introducing his hand into the uterus he coincided with me in regard to the bifid uterus, and we agreed to attempt to deliver the child. The membranes were ruptured and a foot brought through and down. At 4.30 P.M. the second child was delivered alive. It was a girl, weighing five and three-quarter pounds. It was perfect in every respect. The placenta came away within a few minutes, after which the uterus was thoroughly douched with boiled water to which two per cent. of sodium chloride had been added. The mother made a good recovery and at last accounts both children were alive and growing fairly well.

I will now give a history of three former labors, which history I obtained since the birth of the twins.

Patient married October 24, 1883. Age at marriage twenty-three; strong, healthy girl. Has a cousin who had twins.

First child born December 28, 1885. Labor hard and tedious, lasting twenty six hours. Head of child much misshapen. Pressed much to one side. Child born at term; weight two and one-half pounds. Child perfect though very small, has developed into a strong, healthy girl of average size for her age. This child was carried during pregnancy to the right of the median line.

Second child, a boy, born June 8, 1887. Labor lasted six hours. Child expelled precipitately. Mother was not well before labor. Some œdema of the lower limbs. Sallow and weak after confinement. Became quite well after lactation was suspended. Child perfect.

Third babe, boy, born January, 1891. Labor peculiar. Severe pains one week before labor seemed actually to set in. Labor lasted one hour when child was born. Pains unusually severe, child expelled quickly. Child perfect. These two children weighed nearly seven pounds each. Heads were not misshapen in any unusual manner at birth. Both were carried during pregnancy to the left of the median line.

A CASE OF GAS-PHLEGMON.

By BERNARD WOLFF, M.D.,

LECTURER ON DERMATOLOGY IN THE SOUTHERN MEDICAL COLLEGE, ATLANTA, GA.

J. M. S——, is a carpenter, sixty years of age, of small physique and poorly nourished, but enjoying fair health. One week before applying to me for treatment he had accidentally driven a rusty nail into the back of the metacarpal bones of the little and ring fingers. He experienced considerable burning and throbbing pain during the night following the day of the accident, and on the next morning the whole hand was red, swollen, tender, and extremely painful, the inflammation extended up the forearm and arm to a point just above the elbow-joint. It had rather abruptly terminated at this point when I was consulted at the dermatological clinic of the Southern Medical College on December 5th.

The clinical picture presented was that of a phlegmonous erysipelas, in different stages of development. The dorsum of the hand was red, swollen, hot to the touch, and presented a number of vesicles, some of which were intact and contained sero-pus, while others had ruptured, the contents forming loose crusts. In places the epidermis had peeled off, leaving the corium red and shining, and over the wrist joint fissured and discharging sero-pus.

The inflammation had extended up the forearm above the elbow-joint, and had involved the skin and subcutaneous tissue. There were no vesicles on the forearm or arm, which were markedly swollen and hard and tense to the feel and exhibited an erysipelatous blush. The patient complained of burning pain and itching, and there was some general febrile movement. The skin at the dorsum of the wrist and hand was boggy, and produced on palpation the sensation of fluctuation together with a faint emphysematous crackle.

I made some punctures with an exploring needle, intending to locate the pus and then evacuate it by means of free incisions; but I was surprised to note that the needle punctures brought out no pus but were followed by the escape of gas to such an extent that the bulk of the hand was appreciably diminished on compression. A small incision and repeated deep punctures were made, but there was absolutely no pus present except that found mixed with serum in the vesicles and exuding from the fissures. I had, therefore, to deal with a phlegmonous process which had terminated not in the production of pus, but of gas.

The patient was seen by Dr. J. McFadden Gaston, and agreeably to his suggestion was treated with subcutaneous injections of a 12½ per cent., solution of carbolic acid and has made a good recovery.

This affection, under the name of "Gasphlegmon," has been made the subject of a work by E. Fraenkel,[1] of Hamburg.

It appears from his treatise that a diffuse purulent phlegmon must be distinguished from a diffuse septic phlegmon, for the former is characterized by pus formation, the latter by the formation of gas. The two occurring together, behave as a mixed infection.

This observer, from a study of four undoubted cases, claims to have isolated a characteristic bacillus which grows in nutrient agar and forms chains by junction ot terminal processes. It is stained by the Weigert and Löffler methods.

From experiments on lower animals, particularly guinea-pigs, Fraenkel was able to demonstrate positive results from inoculation. This was followed by the formation of gas in the subcutaneous and inter-muscular tissue, accompanied with the development of constitutional symptoms of a severe type, often with the death of the animal. So long as the inoculation was made with a pure culture of the bacillus there was not a trace of pus-formation present. The author therefore concluded that this so-called "bacillus phlegmonis emphysematosæ" was the cause of gas-phlegmon.

Levey[2] reported a case of "gas-abscess" of the thigh, from which he succeeded in obtaining cultures of a bacillus forming chains. It was very short-lived; grew only at the body-temperature, and was stained by the Gram method. He considered this bacillus as the cause of the formation of gas in his case.

I can find no mention of the affection in Brocq, Besnier-Doyon's "Kaposi," nor in any of the works of the English and American dermatologists conferred with.

I have made no bacteriological examination of the case here reported, but have no doubt on clinical grounds of the diagnosis of gas-phlegmon.

Lamnectomy.—Eve says that the operation, if not almost impracticable, is certainly one of the most difficult in surgery, but this is not borne out by present experience. The operation in itself is neither tedious nor difficult. —LLOYD.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, January 6, 1894.

THE MEDICAL PROFESSION AND THE HOSPITALS.

THIS is the time of year when the hospitals of the city recite their deeds to the public and ask for money to carry on their work. It is a time when the question of the utility of this work is presented eloquently to everyone. As a rule, New York responds to the amount of about $50,000. No kind or degree of solicitations is able to raise the sum much above this, and it has in the last year fallen off slightly. New York has forty-seven hospitals, perhaps more if we include the private and semi-private institutions. These hospitals have eleven thousand beds, and the number of patients treated annually reaches up toward a hundred thousand. The number of hospitals and patients treated in them is increasing rapidly. It is safe to say that the amount of work done has doubled since 1875, and there is no sign of a decrease. On the contrary, during the past year large sums of money have been expended in erecting new hospitals or extending old ones.

The same rapid growth has been noted and commented upon in other cities, notably Cincinnati and Philadelphia. In the latter city there are, according to the *Medical News*, thirty-seven hospitals with four thousand five hundred beds, costing $1,300,000 annually. It cannot be denied that the medical profession has begun to look upon this movement somewhat critically, not to say coldly. This is due to several causes. First of all, the treatment of medical men by hospital managers has always been arbitrary, and attended with friction and disturbances. Hospital authorities have heretofore often regarded the medical staff as a kind of necessary evil. They have taken advantage of the fact that physicians have desired to become attached to hospitals, to get as much as possible out of them with as little return as possible. The theory that a visiting staff should be paid for its work has been ridiculed, on the ground that plenty of men can be found who will work for nothing. This theory has a certain economic basis, we admit, but it is not an absolute one, otherwise why should it not be applied to positions of honor everywhere. We could get plenty of congressmen, senators, presidents, and even judges, to serve for practically nothing. But a still more cogent reason for the growth of an antagonism to hospitals is the way in which they deal with the question of charity patients. It is becoming more and more the habit for surgical operations to be done in hospitals. Even well-to-do patients are sent there, paying perhaps nothing, or at any rate a fee very inadequate considering their means and the service rendered. As the *Medical News* says: "Formerly the young doctor had a chance of being called to attend an accident case happening in his neighborhood. Many a physician has won his way into a fair practice through the skill shown in such emergencies. But to-day the patrol wagon or the ambulance is as speedily obtained as the nearest doctor, and the case is whirled off to the hospital. It is treated in the dispensary if a slight case, or sent to the wards or a private room, according as the financial condition of the patient seems to warrant. We have known rich men to pay $25 a week for a private room in a general hospital, and demand extra attention of resident and visiting physicians without ever thinking of remunerating one or the other."

In the smaller cities the case is, we are informed, even worse. We have met well educated and experienced practitioners who have done much surgical work, and done it well, until the building of some small hospital, which is generally under some special political or religious auspices. This killed their surgical work at once. The spread of the hospital system is thus tending to throw a larger amount of medical work every year into the hands of corporations, and the trend is toward a nationalization or municipalization of medicine.

Now, this will certainly be disadvantageous to the physician, for it lessens the amount of his remunerative work, and tends to lessen the general skill of the practitioner. It will make the few skilful, the many unskilful and dependent. For all this physicians will have no right to complain, if the general effect is to be beneficial to the public. If it results in enabling more people to get better medical service at a lower rate, without pauperization or loss of self-respect, then we as good citizens must submit to the inevitable.

In our opinion, however, this will not be the result. If the rewards of the profession become less, its honors more uncertain, a poorer class of men will enter it. If advancement is difficult, ambition will be crushed out. In the end, therefore, the public health will be in the hands of a spiritless and mediocre bureaucracy. Surgeons will be but the machinists of corporations, and physicians clinical clerks to co-operative institutions.

We must deplore now, therefore, as we have in the past, the present tendency to the institutionalism of medicine.

The way out of it, as it seems to us, has already in a measure been begun. It consists in physicians themselves having charge of their hospitals and dispensaries, and in controlling their charitable work. Already two of our teaching institutions have their own hospitals; many, perhaps most, of our eminent surgeons have their private hospitals. The association together of a few physicians and surgeons in good practice enables them to equip a hospital of their own, and renders them independent of the favors of lay hospital boards.

Perhaps this is not the only or the best way to fight against medical institutionalism, but it seems the most practicable at present. At the same time physicians, as a body, should demand more just treatment from hospital authorities, and should protest against the establishment and support of superfluous medical charities.

THE CAUSE AND PREVENTION OF THE INSANITIES ASSOCIATED WITH CHILDBEARING.

The refinements of modern psychiatry have made many distinctions among the puerperal psychoses. This name has been given and is often used to indicate not only the insanities of the puerperal period, but lactational insanity and insanity of pregnancy. German writers make two types of this last form of insanity, one occurring usually during the first three months, the other during the last six.

The puerperal insanity takes at least three clinical types—that of an acute and grave delirium, that of hallucinatory insanity, and a stuporous form known as a puerperal katabonic insanity. For practical purposes, however, the distinctions of puerperal lactational insanity and the insanity of pregnancy are sufficient.

We hear much less of the puerperal insanities than formerly. Marcé's statistics showed that previous to 1860 the number of insanity cases per 1,000 accouchements ranged from 1 to 5½. It was at one time very common in England and Scotland. Clouston states that five per cent. of all the insanity of women is of puerperal origin, and that one case occurs to every four hundred labors. The cases of lactational insanity were next in frequency, being four per cent., while the insanity of pregnancy forms one per cent. of the total admissions of female patients. This is much the same ratio as that given by Esquirol, Marcé, MacDonald, and Gorsky, viz., of one hundred cases one-half would be puerperal, one-third lactational, and one-eighth insanity of pregnancy. It would be interesting to know how time and modern obstetrical methods have changed these figures. Among one hundred insane patients Esquirol found 8.2 puerperals in 1838; Parchappe, 5.5 in 1843; Marcé, 3.7 in 1858, Clouston, 5.0 in 1884, and Mr. Faure, 2.1 in 1890. There can be no doubt of the great decrease in the strictly puerperal class during the past decade. The relative proportion of the different forms has much changed also. The struggle for existence and the consequent worry and care of domestic life have tended to increase the relative number of pregnancy and lactational cases. Such is at least the inference from the statistics of Gorsky, who among 133 recent cases found that 22 began during pregnancy, 55 followed parturition, and 57 occurred during lactation.

Among the exciting causes eclampsia has occupied a considerable place. Among one hundred cases Braun has found mental disorder in 8.3 per cent., Wieger in 7.1, and others in a slightly smaller ratio.

Recent writers have all insisted with especial emphasis upon the importance of the infectious element as a cause of puerperal insanity. The average of a large number of statistics gives about seventy-five per cent. as the proportion of insanities due to some form of septic infection. The tendency of modern observers also is to deny that there is any special psychosis characteristic of the puerperium (Gorsky, Worcester). In a case of puerperal mania, for example, the cause could not be recognized simply by a study of the symptoms. The essential factor is considered to be a psychopathic constitution. A puerperal woman with this vicious tendency develops mania through the toxic agents developed by the inflammatory disorders following accouchement. Thus Madame de Gorsky, a pupil of Magnan, found a predisposition among 33 out of 35 cases of puerperal insanity.

It has been our object in the foregoing to call the attention of our readers especially to the causation of the puerperal psychoses. It is in this field that the most progress has been made; and it is here that the practitioner still needs to make careful observations. It has been shown very forcibly by the experience of the past decade that much can be done in the way of preventing the mental disorders associated with childbearing. The responsibility for this work lies now, and always will lie, with the general practitioner. A woman with a bad hereditary history who marries and becomes pregnant has to be looked after with especial care, in order that she may not be subjected during her pregnancy to undue excitement and depressing emotions. During and after labor the strictest antisepsis must be observed. If she wishes to nurse the child, this must be allowed only when lactation causes no severe drain upon her strength. By proper precautions of the character thus suggested we have no doubt that the number of puerperal insanities can be reduced more than one-half.

THE VALUE OF TUBERCULIN AS A TEST FOR TUBERCULOSIS IN CATTLE.

Probably few physicians are aware of the enormous practical value in the animal industry of tuberculin; that is to say, if the position taken by the New York and other State Boards of Health regarding it is correct. A gentleman who has a valuable herd of thoroughbred cows writes us that twice within the last six months his herd has been examined by competent veterinarians and pronounced healthy. A third examination, however, with the aid of tuberculin, caused a condemnation of over one-half the herd. He adds:

"The New York State Board of Health is killing by the hundred animals condemned by diagnosis with tuberculin, and the State is paying full value for them. The veterinarian says that the autopsy shows the diagnosis to be correct in every case. He says also that it is impossible for the best veterinarian to discover tuberculosis by physical examination except in extreme cases. My herd is apparently in splendid condition. Breeders do not know of its existence in their herds. They let a cow remain in the herd until she is unquestionably tuberculous and then remove her, but she has then already infected the herd. A temperature of 103° F. condemns the cow. In a herd of Jerseys, at Troy, of 80 head, he has killed 33, and will kill 20 more of them this week. Autopsies are held in the presence of physicians and veterinarians. There have been 15,000 tests with tuberculin in England. New York evidently believes in this kind of diagnosis, and will probably have to pay $500,000 to eradicate tuberculosis. The veterinarian says the State is full of it in herds both of thoroughbreds and common cows."

We understand from other sources that the State Board of Health fully believes in the certainty of the tuberculin diagnosis. Through its means it has been discovered that some of the best bred herds, supplying high-priced milk, cream, and butter are infected.

DIACLYSM.

PROGRESS is nothing if not progressive. We have had to modify the ancient rite of clysm by various modern innovations until enteroclysms, hypodermoclysms, tannoclysms, gastroclysms, and similar etymological delicacies have become familiar household words in the medical family. A French savant writing in the *Progrès Médical* proposes the "newest and best" kind of remedial clysm, which he designates as diaclysm, though we infer from his strictly limited experience on living human beings that the victims would be more apt to call it cataclysm.

The energetic Frenchman first demonstrated to his own satisfaction that a corpse would not hold more than three, or at most five, quarts of fluid. If more is forced into a dead body something gives way. A break of the stomach or a rupture of the intestines always occurs. But a living person can be made to hold much more than a corpse—at least "*avec un peu de ménagement et d'encouragement de la part du médecin.*" In plain English, by securely plugging and firmly fixing a rectal tube something like eight to ten quarts can be coaxed into a live Frenchman, though the author hastens to add, "when the bowels and stomach get too full the fluid escapes by the mouth and nostrils." While it cannot be called an agreeable pastime, the author has not hitherto had a death to report. This he finds very encouraging, and he advises his colleagues to diaclyse adults, and young people, and even infants, until a fair diaclysmic record shall have been established for the citizens of the Great Republic. We await statistics with eager expectancy.

All new remedies being peculiarly applicable to cholera, Dr. Antoine de Genersich naturally draws special attention to the value of diaclysm in that ordinarily rather serious malady. We are informed that "les expériences que j'ai faites en mon petit cercle avec l'assistance de MM. les Drs. Jean Maisner jeune, Erdödi et M. Urbanetz à l'hôpital provisoire d'ici, peu nombreuses en vérité, ont donné des résultas très favorables." He does not say that anybody was ever cured of cholera by diaclysm, but still the results were favorable—to diaclysm.

The main point seems to be not to yield to the pitiful moans of the patient who is being diaclysed. For just about when the belly "seems ready to burst," and "the agony of the patient appears almost insupportable," just about that time he begins to vomit, and several quarts of fluid are forcibly ejected from his stomach. All of which shows that the ileo-cæcal valve has been paralyzed and that the fluid has really passed from rectum to mouth. There is a great show of scientific enthusiasm in connection with diaclysm, which we trust will not be fulminated beyond its present boundaries. The average American who holds a pint does not care to be forced to take a quart.

We do not wish to appear ultra-conservative, but for the present when an enema is really needed, we are willing to clysm in the good old way. No doubt the palm of clysmatic perfection must be conceded to France, and in any international clysm-as-you-please contest our Gallic friends would surely win. The author modestly calls diaclysm a triumph of positive therapy. And we do not begrudge him the pleasant glow of gratification which such a triumph must needs beget. "Per diaclysma ad astra" is his motto, or will be, if he does not too soon succumb to diaclysmomania.

News of the Week.

The Medical Department of the Newberry Library at Chicago now contains over twelve thousand volumes.

The Late Dr. Charles Warrington Earle.—Speaking of the late Dr. Earle the *Chicago Medical Recorder* says: "The story of his life is much more romantic than falls to the lot of ordinary mortals. Born in Vermont, at the age of nine years he came to Illinois, and at sixteen was in the volunteer service of the late War, where he distinguished himself not only for bravery but by heroically enduring the hardships, and privations, and sicknesses of campaign, including a number of months in Libby Prison from which he escaped through the famous tunnel. Subsequent to the War he took up the study of medicine, and the rest of his life was devoted to professional work, in which he attained eminence not only as a man of extraordinarily good judgment, but by the local profession he was honored with every distinction within their gift. At the time of his death he was President of the Woman's Medical School of Chicago, the College of Physicians and Surgeons, and the Chicago Medical Society." The *Recorder* adds some most eloquent and appreciative words which show that Dr. Earle held a firm place in the hearts of his brethren of Chicago.

Vaccination Matinees in Paris.—Vaccination matinees have become quite the fashion in Paris. Persons belonging to fashionable society co-operate in arranging to have a doctor and a cow at an afternoon tea. The company are all vaccinated from the cow. In some of the large houses on the Champs Elysées, the cow is taken up in the elevator, and is temporarily installed in the dining room. The cards issued bear the words: "*On vaccinera.*"

The David Livingstone Medical College in London.—Dr. Harford Battersby, formerly a medical missionary in the British dependencies along the River Niger has become the principal of a new medical school in London. The object of this school is to furnish, at the lowest possible cost, the training that will be most useful to intending missionaries, very few of whom are able to spare the years of study and waiting that are essential to the regular English school and qualifications.

New Rush College Laboratory.—Preceded by formal exercises, the doors of the new Laboratory of Rush Medical College were thrown open to the students December 4, 1893. The new laboratory is located on the south side of Harrison Street, opposite the old Rush Medical College. It is a five-story and basement structure with a massive stone front, and cost $95,000. In its interior it is modelled after the most improved plans.

The Richardson Memorial Addition to Tulane University.—The dedication of the New Medical College building of the Tulane University took place November 4, 1893. The building is composed of three connected buildings. The centre one contains principally the lecture-room, having over it the amphitheatre and two wings which contain the laboratories, dissecting-rooms, and museum. The basement is well lighted, and contains a study-room for students, a recitation-room, and an embalming room. The microscopical, chemical, pathological, bacteriological, and pharmaceutical laboratories are

supplied with the latest improvements, and form one of the most complete medical institutions in this country.

Medico-legal Society's New President.—For the first time in its history, the Medico-legal Society elected a medical man, Dr. Hubbard W. Mitchell, of this city, to the presidency of the Society, at its last annual meeting.

The Old Excuse for Cheating the Doctor.—Dr. I. Gutman, a reputable physician practising in the lower wards of the city, was called recently to attend a woman suffering from what appeared to be menorrhagia. After prescribing for her and leaving the necessary directions, he did not hear from her until three days had elapsed. In the meantime she had been delivered of a two months' fœtus by a midwife. He delivered the membranes and washed out the uterus, and the patient having been made comfortable he then requested his fee. Its payment was postponed on a flimsy pretext by the husband. The following day the fee was not only refused, but the husband secured the services of a detective who arrested the doctor for malpractice and the production of abortion. As a consequence the daily papers paraded the fact under the usual sensational head-lines, virtually branding the doctor as a quack and a criminal. The doctor was honorably discharged by the judge. These outrageous proceedings are now offset by a suit on the part of the doctor against the detective for ten thousand dollars damages. Under the circumstances who can be considered safe? Those who know Dr. Gutman and can testify to his good standing and high professional attainments, are at a loss to conjecture why he of all others should have been the victim of such dastardly persecution.

Adulteration of Cheap Wines.—The Board of Health is about to begin another crusade against adulterated wines. Sanitary inspectors have been buying quart bottles of so-called Burgundy, Tokay, and port at many of the small shops on the East and West Side. Some of the so-called wines retail at fifteen and eighteen cents a quart. The authorities know that to keep the stuff from turning sour in process of fermentation the merchants add salicylic acid. A stop has recently been put to this practice in European countries, and it is the intention of the authorities to abolish it here.

The American Psychological Association held its annual meeting in this city on December 27 and 28, 1893. Among the papers read were those on the "Meaning of Infancy," "Do we ever Dream of Tasting," "Pain and Pleasure," and "The Case of John Bunyan."

New York City Vital Statistics for the Past Year.—The estimated population of the city of New York is 1,924,300. The death-rate for last year was 23.46 in the thousand, the lowest on record. The rate in 1877 was 23.65. The sanitary inspections in 1893 were 725,244; tons of food condemned, 2,050; vaccinations, 208,000.

	Deaths.	Births.	Marriages.	Suicides.	Homicides.
1893	44,370	51,516	16,144	313	47
1892	44,329	49,447	16,001	241	32

Diphtheria is about the only contagious disease that shows an increase: 1,963 cases against 526 last year. Police arrests, 1893, 85,612; of these 3,759 were excise arrests; arrests for drunkenness, 20,600; disorderly conduct, 17,486, 5,813 being women; disorderly persons, males, 1,692, females, 830; 2,572 lost children restored to parents; $350,000 of stolen property recovered. Fires, 1893, 4,132; loss, $5,630,937. Only forty-nine fires extended to other buildings than the original.

Appointment to the Buffalo State Hospital for the Insane.—Governor Flower has appointed Dr. William S. Tremaine, of Buffalo, manager of the Buffalo State Hospital for the Insane.

Free Vaccination and State Doctors.—Over two hundred thousand persons have been vaccinated for nothing by the City Board of Health during the past year. Many of those vaccinated were able to pay, and some criticism has been aroused by the extensive and gratuitous labors of the Board. To this it may be answered that the city has a right to protect itself against small-pox as well as yellow fever or cholera. It might, however, in many cases accomplish the result by compelling vaccination by the family physician. Still, we suppose that if the people were to vote to establish State physicians who should treat everyone for nothing, it would be within the people's rights. But it would not be wise.

A Medical Cabinet Minister.—Dr. Bacelli, Professor of Medicine in the Faculty of Rome, has been appointed Minister of Public Instruction.

Municipal Hospital of Philadelphia.—The new pavilion hospital and disinfecting tank has just been completed on the grounds of the Municipal Hospital. The disinfecting plant is one of the most complete structures of its kind in the world, and was erected at a cost of $10,172. In this building all articles used in the hospital will be disinfected. The new pavilion hospital was erected at a cost of $15,352. especially for the treatment of cholera cases, and has accommodations for upward of one hundred patients. It is intended to utilize the structure entirely for the care and treatment of cases of diphtheria, which can be kept entirely isolated from patients afflicted with other diseases. The structure has a number of rooms for private patients, where they may be even more comfortable than at their own homes, and will enable many families to allow their sick to be taken there for private treatment.

International Medical Congress.—The undersigned, Chairman of the American National Committee of the Eleventh International Medical Congress, has received the following communications from the Secretary-General: 1. Papers to be read in any of the Sections of the Congress should be announced on or before January 31, 1894, to the Secretary-General, Professor E. Maragliano, Ospedale Pammatone, Genova, Italy. 2. The title of the paper ought to be accompanied with a brief abstract of its contents and conclusions. 3. The programme to be distributed will contain the titles of all the papers announced before August 31, 1893, and since. 4. The reductions granted by the railway companies months ago will be available from March 1 to April 30, 1894.

In the interest of such medical men as will sail for Europe before official cards will have been received from the General Committee, the undersigned proposes to supply, in as official a form as he thinks he is justified in doing, credentials which are expected to be of some practical value. It is suggested, besides, that a passport may increase the traveller's facilities. A letter from

the Secretary-General, dated November 29th, informs me that "travelling documents" will be sent to the address of every subscriber on or before February 15, 1894; and that after that date congressists will have to apply to the undersigned. It also contains the following regulations of former circulars: Members' dues are five dollars (money-order to Professor L. Pagliani, Rome); guests' (wives and adult relations), two dollars; medical students, no fees. All are entitled to travelling documents. Reductions on the Italian railways are available from March 1st until April 30th.—A. Jacobi, M.D., *Chairman National Committee.*

Dr. Francis Minot Weld died in Boston, December 31, 1893, aged fifty-three. He was graduated from Harvard College in 1860, and after receiving his diploma from the medical school entered the navy as a medical cadet, and served as surgeon on the monitor Nantucket and frigate Wabash. In April, 1864, he entered the army as a surgeon, and was with Grant in the campaign from the Wilderness to Petersburg, and with the Army of the James before Richmond, and joined Sherman at Raleigh. After the war he practised in New York until 1887. He was medical superintendent of the New York Hospital in 1876–77. He was a former President of the Harvard Club of New York, and one of the founders of the University Club of this city. He was for twelve years a member of the Harvard Board of Overseers. He was a member of the Union and University Clubs of Boston, and a member of the Loyal Legion.

An Institute for the Prevention and Treatment of Hydrophobia has recently been opened by the city of Marseilles at the Pharo, close to the present School of Medicine. Dr. Livon has been appointed Director of the new institution which is the first of its kind established in the provinces.

Mortality in the State of New York.—The bulletin of the State Board of Health for the month of November, shows that the reported mortality for the month has further decreased from the low daily average of two hundred and ninety in October to one of two hundred and eighty-one, which is the same as that of November, 1892. This is uniformly the healthiest month of the year in this State, the number of deaths daily being less during November by twenty-five than the daily average for the past eight years. Compared with November, 1892, the zymotic mortality and also the infant mortality are lower; both are also lower than during the month of October. Typhoid fever caused the same number of deaths as a year ago, and seventy-five fewer deaths than in October. Scarlet fever continues with little change to be less prevalent than last year. There is an increase in measles since October, chiefly in New York City. Diphtheria caused the same mortality as in last November, but shows a marked continuance of the increase in prevalence since August, causing one hundred more deaths than in October. The same relative increase occurred in 1892. Small-pox exists outside of the metropolitan centre, in Warwick, Greensburgh, and White Plains, where single cases are reported, and at Islip, where two deaths occurred. There were 955 deaths from consumption, against 1,070 in October; there are uniformly fewer deaths from it at this season. Acute respiratory diseases have, as usual, increased, the mortality being 1,242, against 947 in October. Another return of epidemic influenza has occurred, but has not impressed itself upon the mortality of the month, though a few deaths attributed to it were reported. The death-rate for the month from all causes is 15.35, against 15.83 in October.

Governmental Regulations Concerning the Management of Typhoid Fever.—The Government of the Grand Duchy of Baden has recently issued a series of regulations as to the management of cases of typhoid fever, of which the following deserve to be mentioned: Cases of typhoid fever shall be strictly isolated; the patient's stools, as well as all linen and water which have come into contact with him, shall be disinfected; no one shall be admitted into the sick-room with the exception of the relatives of the patient, physician, nurse, priest or minister of religion, and notary. In fatal cases none but the near relatives, physician, and undertakers shall be allowed to approach the body of the deceased. In the event of several cases of typhoid fever occurring in the same house, if the means of isolation appear inadequate and if there be any reason for apprehending an epidemic, the police authorities shall have the right, on application being made by the physician in charge, to prohibit the admission of all strangers into the house; a special notice to that effect shall be posted at the door of the infected house.

Increase of Suicide in France.—A study of the number of suicides in France reveals a most deplorable state of affairs. According to the *Journal Officiel*, during the year 1890 this number reached the formidable figure of 8,410 (6,576 males and 1,834 females). These figures indicate a progressive increase in the number of suicides. In the quinquennial period from 1861 to 1865 the average annual number of suicides were 4,661 (12 per 100 000 of the population); while during the period from 1886 to 1890 the average annual number was 8,226 (or 21 per 100,000). The proportion of suicides among children under the age of sixteen years has also increased. While in the period from 1871 to 1875 the number was 31, it was in 1886, 62; in 1887, 68; in 1888, 65; in 1889, 77; and in 1890, 80.

How School Children Communicate Disease.—Dr. Moreau Morris, of the Board of Health, has presented a report showing the result of his investigation of certain common practices in public schools. Dr. Morris has found that in all the schools he visited the children used the slates and pencils in common. The children are in the habit of putting the pencils in their mouths, and in that way communicate the diseases. Dr. Morris condemned the use of slates in the schools altogether. He also recommends that books which have been used by children who were sick should be destroyed, and that paper book-covers should be substituted for muslin.

New Hospital.—The Baptists of Boston, under the leadership of Rev. Everett D. Burr and Dr. Francis F. Whittier, have determined to establish a hospital under the auspices of that denomination.

An American Dentist for the Czar.—Dr. Wassail, of Chicago, has been appointed court dentist at St. Petersburg, and will go in February to his new post. With him will go his young wife, who writes cleverly and is a musician.—*Journal of American Medical Association.*

Society Reports.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, December 1, 1893.

CHARLES L. DANA, M.D., PRESIDENT, IN THE CHAIR.

Instrument for Evacuating and Draining Pelvic Abscesses.—DR. CLEMENT CLEVELAND presented such an instrument, which was a combination of trocar, dilating forceps, and drainage tube.

DR. CHARLES MCBURNEY thought that ordinarily, unless there were serious contra-indications, the general rule which called for removal of the sac of the abscess where this was possible, was a good one—better than that of simple puncture and drainage. There were, of course, as the author had said, cases in which removal of the sac would be attended by special dangers and should not, therefore, be undertaken; in such cases the method of establishing drainage described in the paper would be appropriate. He had not understood the author himself to suggest, but only to raise, the question whether it would not be a valuable substitute for excision of the sac in all cases.

DR. ROBERT ABBE thought the principle a correct one in dealing with large tubal or pelvic abscesses. It was true that pyosalpinx implied stenosis of the uterine end of the tube, but that stenosis might be only temporary. He had seen cases of well-marked salpingeal abscess which had evacuated through the uterine cavity, implying a reopening of the stenosed tube. There was no reason why the pus-sac, even though having a mucous lining, should not heal if the contents were drained off for a few weeks. The principle of the treatment was one which nature endorsed by healing the mucous lining, and if the stenosis on the uterine side should not reopen it was still intelligible that the diseased portion of the sac might, after evacuation and drainage, heal up perfectly. It seemed to him, therefore, that the surgical principle involved was a correct one, and that the method was especially applicable where the abscess was well down in the cul-de-sac. He had had one such case treated by drainage three or four years ago, the opening having been made with a knife, and the patient got well. He thought Dr. Cleveland's instrument an ingenious one and perfect in its way.

DR. R. F. WEIR said his experience with the class of cases under discussion had not been great, but it seemed to him that, ordinarily, puncture and drainage could not take the place of excision of the sac. The drainage in abscess of the pelvis was attended, in the first place, by the difficulty and danger of tapping the sac and inserting the tube. While he regarded the ordinary method of excising the sac the better one, yet cases must arise where this could not be applied, and in them the instrument shown by Dr. Cleveland would prove useful. That its use was attended with some danger was shown by the author's suggestion, to make an abdominal incision in order to be able to appreciate when the end of the trocar had reached the farther wall of the abscess. But it was not always easy to obtain consent to opening the abdomen solely for the purpose of guarding against a possible accident during an operation. The instrument itself had been excellently devised, but the principle was an old one and had been embodied by the French in instruments made to puncture and drain the kidney, etc.

DR. CLEVELAND said he would not be understood as advocating the use of drainage in this way for all cases of pyosalpinx. The statement at the conclusion of his paper had been added merely as a query to call out discussion. The instrument had been devised only for the purpose of evacuating abscesses where the intestinal adhesions were so firm that it would be impossible to remove the diseased tube without causing the death of the patient.

Some Points in the Diagnosis of Appendicitis.—DR. GEORGE F. SHRADY read the paper. (See page 1.)

Importance in Diagnosis of Eliciting Seat of Greatest Pain, and History of Previous Attacks.—DR. CHARLES MCBURNEY remarked that the subject was an extensive one, and he felt like congratulating Dr. Shrady on the thorough manner with which he had covered the ground that he had undertaken to cover. In his own experience he had been very much struck by the fact that, on inquiry being directed especially to the point, the patient very often acknowledged having had repeated attacks, though not violent ones, or they would have been mentioned without inquiry.

It seemed to him that such papers as had just been read spread a knowledge of the subject so far that the diagnosis had come to be very constantly made, even by men practising in the country, where they might be supposed to have very little experience with this special class of cases. But where doctors made a very serious error, not only in the country but also right in New York City, was in estimating the time when action was required. They made the diagnosis of appendicitis; they told the friends what the trouble was; they laid out a plan of treatment which they recognized as appropriate to that particular disease; but then they seemed to stop, failing to take in fresh observations as to the time when an operation should come in. He had seen that occur over and over. Just that day he had operated in a case where one of two physicians wanted the operation held back until the third day, while the other wished to postpone it until the fourth day. Although they did not think the time had come for operation, yet after this was done the pelvis was found to be full of septic fluid. They had recognized the disease, there was no difference of opinion upon that point, but they had no idea that the process had gone on to any grave extent; whereas the entire appendix was gangrenous, an abscess had formed, had ruptured, and the material had drained down on the intestines.

Yet when one tried to write a valuable guide in determining the exact time for operating, he found it exceedingly difficult. The speaker had himself been guided a good deal by the condition of the pulse. In appendicitis with advancing changes it was almost certain to be of a hard, inflammatory character. It had also seemed to him that the point of greatest tenderness, as elicited by careful examination, was of great diagnostic importance. A patient with mild appendicitis might not complain much more on pressure over one point than over another, but when the inflammation became acute he would complain strongly when pressure was made over the right place. Those two facts had aided him greatly in making out the grade of the process.

He cordially endorsed what had been stated in the paper with regard to the value of rectal examination as suggested by Professor Loomis. Dr. Lange had strongly endorsed the value of that procedure, yet Dr. McBurney's experience had led him to believe that it was useless. In one or two cases of old abscess of three or four weeks' duration, rectal examination had shown burrowing down toward the anus, but such cases, of course, were unusual. The danger of bimanual examination, as shown by Dr. Shrady, should not be overlooked. That adhesions around the appendix might be ruptured by such manipulations was evident, from the fact that they sometimes ruptured spontaneously.

A Successful Rectal Examination.—DR. HENRY F. WALKER said that several years ago, before operations upon the appendix were so frequent, a patient was under his care, in association with Drs. Thomas, Metcalf, and Sands, on whom he made a rectal examination and was able to make out a very interesting state of things. The whole pelvis was so filled with effusion that it was walled over as far as he was able to touch, the feeling being precisely like that on introducing the finger into the vagina of a woman suffering from extensive pelvic peritonitis. Everything was bound down by the effusion. This woman recovered.

Dr. Walker had observed as a rule precursory looseness of the bowels rather than constipation in appendicitis. When the disease became fairly established and pain had

set in, constipation succeeded the mild diarrhœa. He had been impressed very much by the epigastric pain as initiatory of the disease in many cases. It became evident on pressure over that region. He had spoken of that to Dr. McBurney, who told him that Dr. Bacon, of New Haven, when exploring the abdomen of a patient under cocaine, made pressure upon the appendix, and immediately the patient complained of pain in the epigastrium. Evidently, therefore, there was a nervous affinity between the two places.

Where the Appendix is Found Healthy, is the Operation Liable to be Followed by Symptoms?—Dr. George L. Peabody inquired of those who were operating frequently whether they had ever witnessed any damage follow an operation in a case of mistaken diagnosis. Some years ago he had requested a prominent surgeon to see a patient with him whom he believed to have appendicitis. The surgeon concurred in the diagnosis and an operation was done, but the appendix was found healthy. Fortunately no harm resulted. Yet the possibility of symptoms arising after operative procedure was suggested by a case in which, at his request, a surgeon operated and found gangrenous appendicitis and abscess, and the patient returned six months afterward, complaining of pain in the region of the scar and of indigestion. There was no hernia. Would not intra-abdominal adhesions account for the pain in that case?

Dr. Robert Abbe said the points in diagnosis had been so well covered in the paper, that he would only mention one on which he had laid a great deal of stress, namely, the condition of the pulse as indicating the gravity of the case. It was distinctly hard and snappy in the graver states. Regarding rectal examination, he had made this pretty uniformly, and had found that in the exceptional cases where the inflamed appendix hung over the brim of the pelvis, it could be felt with the finger introduced into the rectum, as could also abscesses which had descended into the pelvis.

Dr. R. F. Weir thought the paper contained a very graphic description of a disease which, according to his observation, had come to be pretty uniformly diagnosticated in and around New York. The main features, including especially rigidity of the abdominal walls in the right iliac fossa, gave quite a satisfactory basis for diagnosis. The author, however, had mentioned one other point in connection with diagnosis which seemed of some importance. It was one which men had floundered over ever since the subject of appendicitis had come to the front, namely, that many cases which the practitioner saw recover were not appendicitis but cæcitis or typhlitis. It had seemed to Dr. Weir for many years, that if this were so he would occasionally, on opening the abdominal cavity for supposed appendicitis, find not appendicitis but cæcitis; yet as a matter of fact he had not met with a single case of the kind, neither in his own practice nor that of his colleagues. He would also say, as a matter of observation, that he had seen the cæcum filled with fæces in only one case. Ordinarily the cæcum had been comparatively empty, or distended moderately with gas or with some fluid or soft fæces.

The diagnostic point with which Dr. McBurney's name had been associated was, to his mind, a very valuable one, with this particular restriction, that the point of greatest pain be brought out by pressure with the tip of a single finger. In his opinion it was not so important that the seat of greatest pain be elicited at one particular point between the umbilicus and anterior superior spinous process, for the reason that inflammation, the cause of pain, was more likely to involve the appendix at some distance from its fixed point, which was the root.

While the matter was somewhat aside from the subject of discussion, diagnosis, yet when "the red rag of appendicitis" was raised before surgeons, they could not resist the temptation to impress the fact that the point of greatest importance to the public was early operation. The objection was made by physicians, that when the surgeon operated early the patient was not given a chance to throw off his trouble without such interference. As bearing on this question, he had taken some pains to collect statistics of cases treated medically, and others treated surgically, and compared their mortality-rate. The number of cases which he had thus far collected was too small to base upon them positive conclusions, but he had found that in one hundred and thirty cases of appendicitis treated medically, the mortality had been five per cent. In about two hundred cases operated upon early, say within forty-eight hours, by surgeons of experience, the mortality had been also about five per cent. This showed, he thought, that the surgeon did not diminish the patient's chances of recovery by operating too early. This brought him to the question which Dr. Peabody had raised, whether the surgeon did not find from time to time a healthy instead of a diseased appendix. Personally, he had not met with that experience. He did once remove a healthy appendix in conjunction with an abscess of unknown origin, thinking that it might possibly have been the cause of trouble, or would be in the future. Aside from that case he had never removed the appendix whose diseased condition did not justify the resection. On inquiry among his colleagues, he had not found that they had met with mishaps of the character alluded to.

The Inconstancy of Collapse in Perforation.—Dr. Weir agreed with Dr. McBurney, Dr. Abbe, and Dr. Shrady in laying a good deal of stress upon the condition of the pulse in deciding when to operate. Some time ago a physician in this city stated quite positively, as medical men were apt to do when it came to surgical matters, that one ought to be able to tell, and he could himself always tell, when there was perforation of the appendix by the shock, collapse, etc.; yet those who did the operating saw a great many cases of gangrene and of perforation where there was no marked collapse. There might have been localized pain or some very tender spots, but many patients did not have collapse. He had seen very few cases where there was such an amount of shock as to give warning that something very serious had taken place.

With regard to the question of general pain, it was true that frequently there was for some hours so much general pain over the abdomen that one could not make an exact diagnosis: but by waiting, though not longer than forty eight hours, localized pain would either show itself, making the diagnosis positive or there would be diminution of the symptoms, making an operation unnecessary, or an aggravation which would decide an operation at once. When he found the temperature going down, the pulse becoming more moderate, the vomiting having ceased, the abdominal tenderness less marked, he would withhold the knife. But there must be coincident improvement throughout the whole circle of these symptoms to lead him not to operate. If all improved but one, or especially two—if, say, the pulse and temperature kept up, it would mean operation.

Regarding pain subsequent to an operation for appendicitis—the question raised by Dr. Peabody—Drs. Weir, Abbe, and McBurney said they had not encountered it. Dr. Weir thought Dr. Peabody's explanation of the pain in the case to which he had referred, was probably the correct one, namely, that it was due to the formation of adhesions.

Dr. Shrady being called upon to close the discussion, said he thought the remarks which had been made were corroborative of what had been stated in the paper. At least he had no particular objection to make to them. With reference to the matter of recurrence, of course that had been recognized in the paper as one of the main indications, and had been incidentally referred to in connection with the different diagnostic indications. It had always been a matter of importance in his opinion, yet one must expect at some time to meet with a case during the first attack, when the symptoms were such as to call for an immediate operation. Dr. Walker's remarks with reference to pinching the appendix, whereupon the pain

was referred to the epigastric region only, proved that it was a reflex pain, as had been stated in the paper.

The character of the pulse being snappy, referred to by Dr. Abbe, he had always looked upon as indicating progressive inflammatory trouble, and had taken it as a pretty good guide for operation. A sudden change in the pulse, coincident with other grave symptoms, was a very important element in diagnosis.

He had been not a little surprised to hear that Dr. Weir did not believe so much in cæcitis as other people do, but he supposed it was to be explained partly on the ground of his luck in not having run across the condition in his many abdominal operations.

Dr. Weir interjected that he had not seen it when operating for appendicitis, but he had observed it in other inflammatory conditions.

Dr. Shrady went on to say that he had seen cæcitis in five cases within the last two years, and the patients got well without operation, although this had been thought of. Three of the cases were in elderly females, two in adult males.

He had expected some one would question the diagnosis of the appendix by touch through the abdominal walls, for he had not supposed this possible until it had been suggested to him to make steady pressure until resistance was encountered from the posterior walls, when, if the appendix were present in that locality, it might be felt as a cord rolling under the finger. Probably this would be possible only where the appendix was turgid and bulbous, as it was in one case in which he mapped out its location, and on cutting down found it directly under the mark made on the abdominal wall, about two inches and a quarter from the anterior superior spine, in line with the umbilicus.

Surface Hyperæsthesia Corresponding to Disease of Internal Organs.—The President, Dr. Dana, said that an English observer had studied a large number of cases in trying to map out what he called reflex hyperæsthesia from disease of the viscera in the thorax and abdomen. The article, a voluminous one, was published in *Brain* about a year ago. Charts and figures were given to indicate the change in the condition of the skin or dermal nerves corresponding to lesions in different parts of the intestine, in the kidneys, spleen, liver, and thoracic viscera. The theory advanced was that in serious inflammatory or irritative condition of the viscera, careful tests would show a change of reaction of the nerves on the surface, so that, for example, if the blunt end of a pin was carried carefully down from the upper part of the thorax to the lower part of the abdomen, an area of pain or discomfort would be found corresponding to visceral disease marked on the map. The President had been able, by the seat of the chronic pain in one case which corresponded to a certain region pointed out in the map, to locate the disease in the kidney, and subsequently Drs. Polk and Edebohls both diagnosticated prolapsus of that organ. The method had also been of some value to him in certain other cases, and it had occurred to him that in doubtful appendicitis it might be found of use. In the chart referred to, however, no reflex area had been given for the appendix, but perhaps by careful tests one might be found.

Hemorrhage is a very common accompaniment of malignant disease of the tonsils. A solution of antipyrine, 1 part in 50, may be used as an hæmostatic. Should such treatment not succeed, then ligature of the base of the tumor, either by one ligature or by several, may be resorted to, or cauterization by the thermo- or galvano-cautery. In the event of none of these means succeeding, ligature of the lingual and facial arteries may be required, or, as a *dernier ressort*, the carotid may be tied.—Newman.

The Boutonniere operation should be performed in enlarged prostate only where the catheter cannot be introduced, or where septic urine must be let out. If cystitis, do the suprapubic operation.—Vignard.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 8, 1893.

H. P. Loomis, M.D., President, in the Chair.

Van Gieson's Picro-acid Fuchsin as a Selective Stain for Connective Tissue.—Dr. George C. Freeborn presented the following communication on this subject, with illustrative specimens:

In 1889 Van Gieson[1] described a method of staining the peripheral nerves and sections of the central nervous system with a mixture of picric acid and acid fuchsin. He prepared his staining fluid by adding a saturated aqueous solution of the acid fuchsin to a saturated aqueous solution of picric acid, until a deep garnet-red colored fluid was obtained. This staining fluid stained the ganglion cells, axis cylinders, neuroglia, and sclerotic areas red, and the myelin yellow.

Ernst[2] has used this fluid for staining the central nervous system, and recommends it highly. This recommendation is seconded by v. Kahlden.[3] Ernst[4] also found it a useful stain for hyalin degeneration, which is stained deep red. This reaction for hyalin has been confirmed by v. Kahlden,[5] who also found that hyalin and colloid could be differentiated in the same section, hyalin staining a deep red, while colloid is but slightly tinged, or is stained yellow.

Van Gieson's fluid was not made up with any definite proportions of the acid fuchsin solution, consequently the results obtained with each new sample of the fluid differed from those obtained with the previous ones. In order to fix the proper amount of acid fuchsin to be added to the picric acid solution, I commenced a series of experiments. While conducting these experiments I found that the acid fuchsin showed a selective action for fibrillated connective fibres, staining them a bright red. This led me to try the action of the staining fluid on other than nervous tissue, and I found that in all organs the connective fibres always gave the same reaction; no matter how fine, they were stained a bright-red color.

As the results of my experiments I have succeeded in establishing the following formulæ for the staining fluid:

For connective tissue the proportions giving the best results are 5 c.c. of a one per cent. aqueous solution of acid fuchsin to 100 c.c. of a saturated aqueous solution of picric acid. For sections of the central nervous system the proportion of the acid fuchsin has to be increased and that of the picric acid diminished. The elements in this tissue stain more slowly, consequently the prolonged action of the picric acid removes the hæmatoxylin from the nuclei. The proportions of the staining agents that have given me the best results are 15 c.c. of a one per cent. solution of acid fuchsin to 100 c.c. of a half-saturated solution of picric acid.

Sections of tissues hardened in Müller's fluid or mercuric chloride solutions—alcohol hardening does not give as brilliant results—are first deeply stained in hæmatoxylin (v. Kahlden recommends alum carmine), and then well washed in water. They are then placed in the picro-acid fuchsin fluid for from one to three minutes. Sections of the central nervous system require fully three minutes, those from other organs, as a rule, require only one minute. After removing the sections from the staining fluid, they are washed in two alcohols. I find that the addition of a small amount of picric acid to the second alcohol increases the brilliancy of the yellow stain. The sections are cleared in oil of origanum cretici and mounted in balsam.

This staining fluid, when used as above described, stains connective-tissue fibres a bright red: protoplasm, muscular tissue, and red blood-cells, yellow. The hæmatoxylin stain in the nuclei is usually changed in color: sometimes it shows purplish red, at other times black.

I present the following sections in illustration of the

[1] New York Medical Journal, July 20, 1889.
[2] Virchow's Archiv, cxxx., 1893, p. 279.
[3] Centralblatt f. Allgem. Pathol. u. pathol. Anat., iv., 1893, p. 456.
[4] l. c., p. 377. [5] l. c., p. 457.

action of this staining fluid; normal spinal cord, cerebellum, syringo myelia, and tabes, in which the tissue-elements are stained as described by Van Gieson. As illustrating its action on connective tissue, pig's liver, in which the connective tissue bands between the lobules are brought out sharply, even to the naked eye. Human liver, human prostate gland, in which there is a sharp differentiation between the smooth muscle and the connective tissue. Human skin: in this preparation the deep-red papillæ stand out sharply against the yellow colored epidermis. Corpus luteum of pregnancy. Carcinoma of the mamma. Large spindle cell sarcoma. Fibro-myoma of the uterus, in which there is a sharp differentiation between the smooth muscle and connective tissue. Intra cartilaginous development of bone; this section gives the most brilliant picture of the series. The matrix of the hyaline cartilage is stained a light purple color, the cells yellow with purplish nuclei; the calcification zone is of much more deep purple as well as the cartilaginous remains enclosed by the new-formed bone, which is of an intense red; the connective tissue is of a lighter shade of red than the bone, and the red blood-cells bright yellow.

Appendix.—Since reading the above, Kantorwicz[1] has published the results of his use of this staining fluid. He finds that the proportion of the acid fuchsin added to the picric acid is of importance and gives the following formula of the solution used in the laboratory of Dr. Schurhoff, in Frankfort-on-the-Main: Saturated solution of picric acid, 150 parts; saturated solution of acid fuchsin, 3 parts.

He recommends that the sections be stained in Delafield's hæmatoxylin for half an hour, and then in the picro-acid fuchsin for from three to five minutes. He has also found the stain useful for tumors, the nuclei staining a purple, protoplasm a bluish yellow, necrotic tissue yellow, connective tissue red. In carcinoma he found that the connective-tissue fibres between the cell-nests were brought out sharply. He also recommends the stain for cell-inclusions. The inclusions stain darker than the protoplasm and stand out sharply.

The President asked with reference to the permanency of the stain.

Dr. Freeborn replied that he had had some specimens upward of two years, and the coloring had not faded. Sometimes prolonged immersion in the oil of origanum would bleach out the acid fuchsin.

Carcinoma of the Cardiac Orifice of the Stomach.—Dr. Hodenpyl presented a specimen of carcinoma of the cardiac orifice of the stomach, which had been removed from a case in which there were some unusual symptoms during life. A man was found in the street spitting blood. He was brought to the hospital in an ambulance, and died in about fifteen minutes. Just before his death he vomited a large quantity of fluid blood. At the autopsy, it was noted that he appeared to be about sixty-five years of age, and possessed an unusually good physical development. All the organs were exceedingly pale. The stomach and upper portion of the small intestine were greatly distended with clotted blood, and the stomach was filled with a clot having the shape of this organ. An ulcerating carcinoma measuring four by three inches completely encircled the cardiac orifice, and the opening only admitted the tip of the finger. The head of the pancreas was also the seat of an ulcerating carcinomatous mass. The interesting point in the case was the entire absence of emaciation.

Hypertrophic Cirrhosis of the Liver.—Dr. Hodenpyl also presented specimens from a case of hypertrophic cirrhosis of the liver. The patient was a man, thirty-eight years of age, who, although very intemperate, had been in fairly good health up to three months ago, at which time he began to have jaundice and anasarca. Subsequently he complained of nausea and headache, and he developed ascites. On admission, two days before his death, there was extreme abdominal dropsy. He was tapped, and a large quantity of fluid removed. He then passed into a condition of stupor, which quickly deepened into a coma from which he never roused. At the autopsy, the principal object of interest was the liver, which weighed nine pounds. It was very rough, jaundiced, and cut like paraffine

A section of the liver was exhibited under the microscope. It had been stained by Van Gieson's method, and showed the connective tissue well.

Congenital Syphilis.—Dr. R. G. Freeman presented specimens from an infant, aged about six weeks, who died in the Foundling Asylum. It was in poor condition when admitted on October 17th. On October 27th, there was slight dulness over both lungs posteriorly, the respirations were 90, the pulse 150, and the evening temperature 101.4°F. For the next three days the respirations remained about 90, and the temperature, though elevated, did not exceed 101.5°F. A diagnosis was made of pneumonia over the posterior portion of both lungs, and there was a suspicion of tuberculosis. At the autopsy, it was found that the posterior portion of all the lobes of both lungs was consolidated in a peculiar manner, and that the liver was the seat of numerous small nodules resembling tubercle. A microscopical examination of these showed them to be small gummata. The other portions of the liver showed marked fatty degeneration.

Malformation of Hands and Feet.—Dr. Freeman also exhibited specimens taken from an infant, aged two months, who had suffered from marasmus. All the fingers of the left hand were webbed, and there was a rudimentary finger. Each foot had six toes, and four of these were webbed.

Bevan Lewis's Staining for Ganglion Cells.—Dr. Ira Van Gieson presented specimens showing the results obtained with Bevan Lewis's method of staining ganglion cells in the cortex.

He said that the fundamental importance of technical methods was nowhere better shown than in the successive eras of development of the anatomy of the nervous system. Every important advance in this department had had for a basis some valuable improvement in instruments or in staining. To-day, we know that the cortex is one vast wilderness of processes, protoplasmic and neural, derived from the ganglion cells. The ganglion cell had received rather tardy recognition from biologists. This cell consists not only of protoplasm and nucleus, but is a very complex cell. We are beginning to homologize all these intricate parts of the ordinary cell in the ganglion cell, and as a result of regarding the ganglion cell from this standpoint may be instanced the brilliant work of Hodge, who has been able to formulate a sort of mechanical equivalent for the work done by a ganglion cell during fatigue and the recovery after fatigue.

In view of all these rapid advances in our knowledge of this cell, both as to its form and physical structure, we can realize how imperfect are the methods by which we endeavor to ascertain the more delicate changes in cortical pathology. The conventional method is to harden large masses in Müller's fluid. This very crude, perhaps even worthless, method only shows the cell body of the ganglion cell. Müller's fluid was long ago shown to be a very poor preservative of the ganglion cell; the shape, processes, etc., are not shown at all in a specimen thus prepared. In the specimens stained according to Bevan Lewis's method, on the contrary, the structure of the protoplasm and nucleus is nearly perfect. The cortex is so impervious to fluids that, in large masses, active degeneration takes place in the interior of the specimen before the fluid reaches this part. Professor Donaldson has found that portions of the cortex increase in volume twenty-five per cent. during their immersion in Müller's fluid, probably because the myelin and the ganglion cells both absorb water from the fluid.

The method described by Bevan Lewis in his book, and also published in the *Journal of Insanity* for July, 1892,

[1] Centralb. f. Allgem. Pathol. u. pathol. Anat., October 31, 1893.

is very simple. Portions of the cortex are frozen; then transferred to a one-fourth per cent. solution of osmic acid for ten seconds; rinsed with water, and stained for half an hour or one hour in a one fourth per cent. solution of aniline blue black. Then the specimens are dried overnight on a slide, or more quickly, in an oven. The freezing is quite simple at the present time, because liquefied carbonic acid gas is now readily obtained. Specimens may be frozen with it in half to one minute in a freezing microtome provided with a shallow chamber.

The cerebellum and the spinal cord do not behave well with this method; the former becomes fragmentary, and the myelin of the spinal cord swells up in the osmic acid solution.

Dr. Freeborn said that aniline blue-black was an old and favorite stain with Bevan Lewis, who many years ago published a method which showed the ganglion cell much more sharply than had been done up to that time. The plan was to over-stain the specimens in aniline blue-black, and then to place them in oil of cloves and chloral until, when viewed under the microscope, the intercellular substance was found to have been bleached out. He had himself prepared a number of very satisfactory specimens in this way; he thought, however, the acid fuchsin fluid would act very similarly to the aniline blue-black, but would probably give a more brilliant stain. It is certainly most admirably adapted to photographic work.

Tubercular Appendicitis.—Dr. H. S. Stearns presented specimens from an obscure case of appendicitis of tubercular origin. The patient was a man, thirty-six years of age, both of whose parents had died of phthisis. He was first taken sick on August 4th, with a chill, and severe headache and backache, and considerable epigastric pain. In the course of the next few days there were repeated slight chills, followed by fever, and increased and more general abdominal tenderness. About two weeks later he developed an obstinate diarrhœa of a typhoid character. On September 12th the morning temperature was 101° F., and the evening temperature 102° F., and the pain was more marked in the right inguinal and lumbar region. Appendicitis was thought of, but was excluded because of the widely diffused tenderness. A diagnosis was made of typhoid fever. The diarrhœa resisted all medication, and on November 4th the patient died. At the autopsy the brain, heart, liver, and kidneys were found normal. Both lungs were studded with miliary tubercles, and the left lung contained an old cavity, and was very firmly adherent to the costal pleura at its apex. The spleen was twice the normal size, and contained many miliary tubercles. Tubercular ulcers were found in the lower portion of the ileum, and in the cæcum and ascending colon. The appendix was considerably swollen at its lower end, and contained about a drachm of dark-colored pus. Its interior showed numerous miliary tubercles.

The question naturally arose, would the patient have been benefited if an early correct diagnosis had been made, and an operation performed?

Dr. Hodenpyl thought miliary tubercles were not infrequently found in the appendix, but he did not think this condition often gave rise to the symptoms ordinarily associated with what is called appendicitis. He could not see how an operation would have benefited the patient.

Dr. George P. Biggs thought it quite possible that there had been an appendicitis at some remote time without marked symptoms, and that subsequently there had been a deposit of tubercle. Quite recently he had seen a case of intestinal tuberculosis in which the appendix was enlarged and the mucous membrane ulcerated.

The President said that he had watched the progress of the case now under discussion, which was of interest clinically from the fact that the patient was supposed to have typhoid fever up to the sixth week of the illness.

Cerebral Hemorrhage.—Dr. E. D. Fisher presented a brain removed from a man sixty one years of age, who was admitted to Bellevue Hospital on October 21, 1893. There was no distinct history of syphilis, and he had not been intemperate for many years. On October 16th, while driving, he suddenly lost control of the muscles of the left arm and hand. This was quickly followed by complete hemiplegia, facial paralysis, and loss of consciousness. When admitted to the hospital he was comatose, and the left side of the body was cold. His pulse was 70, and full; respirations, 24, deep and stertorous; temperature, 95.8° F. It was not possible, owing to the condition of the patient, to say positively whether or not there was marked anæsthesia. For several days there was a low, muttering delirium, and finally distinct rigidity of the muscles of the back of the neck. Later on he developed large bed-sores, the pulse became rapid and feeble, and the temperature rose; and he finally died on October 30th. The speaker said that he at first made a diagnosis of thrombosis or slight hemorrhage, but as the symptoms increased he concluded that there had been a renewal of the hemorrhage. The autopsy showed extensive œdema of the pia mater covering the cortex and convolutions, and extensive arterial degeneration and calcareous deposits in the arteries of the base. There was a blood-clot about two inches in diameter, involving the posterior portion of the internal capsule and lenticular nucleus, and extending to, but not involving, the optic thalamus. There was yellowish-brown softening of the surrounding parts. The heart and aorta were the seat of atheroma; the lungs were emphysematous, and the kidneys cirrhotic.

Considering the size of the lesion, the symptoms corresponded very well with the situation of the clot. The speech was not so much impaired, or the paralysis so extreme, as in cases where the lesion is more anterior. It is just possible that there was first a thrombosis, and that the consequent softening deprived the diseased blood-vessels of their proper support, and led to the hemorrhage. The œdema is probably explained by the compression exerted by the blood-clot, causing exudation of the watery elements of the blood.

Dr. H. P. Loomis presented two brains taken from persons who before their death had complete paralysis with loss of sensation and motion on the left side. The first specimen was from a woman, thirty-six years of age, who died two hours after admission to the hospital. The lesion in this case was a pachymeningitis hæmorrhagica interna. The second specimen was removed from a woman, forty-four years of age, who was well up to three days before her death. At this time she became suddenly paralyzed, and was partially comatose when brought to the hospital. On the following day she developed a typical Cheyne-Stokes respiration. The autopsy showed an internal hemorrhage which had destroyed the corpus striatum, internal capsule, and part of the optic thalamus.

The Society then went into executive session.

Excision of Rectum.—(Kraske.) The incision commences in the middle line beneath the coccyx, and terminates about the centre of the sacrum, inclining slightly to the left. Enucleate the coccyx; remove with cutting pliers a fragment of the left side of the sacrum, at first very little, subsequently enlarging if more space is required. Go straight to the rectum through the cellular tissue, tying the vessels. Open gut and remove diseased parts by fragments with care. Resect in totality. If peritoneum is opened, close with points of suture. Suture severed extremities of intestine together.—Richelot.

Strangely Marked.—Of the many strange results of impression reported from time to time few equal the following from the *Indianapolis Sentinel:* Previous to the child's birth the mother refused to speak to her husband for several weeks after they had quarrelled; when the boy began to talk it was noticed that he never spoke to his father. Punishment failed to elicit a word, and not even a cry. The boy is now ten years of age, and although on friendly terms with his progenitor, finds it impossible to address a word to him.

Therapeutic Hints.

Gonorrhœa.—

℞. Antipyrin..... gram. 10
Bichloride of mercury..... centig. 10
Water..... gram. 1000
Sig.: Inject and let remain in canal for half an hour.

—Watier.

Parenchymatous Orchitis in variola is not at all rare. Its development keeps pace with the exanthem upon the skin, and so is probably of the same nature.—Chiari.

To Abort Gonorrhœa.—Wash out anterior urethra for four days with 1 to 4,000 permanganate of potassium.—Jamin.

Impotence in sexual neurasthenia, suspension in Sayre's apparatus. In masturbation and pollutions, hypnotic suggestion.—Gvurkovecky.

Vulvo-vaginitis in Young Girls.—

℞. Sulphate of copper..... gram. 2
Glycerine..... " 20
Water..... " 80
Inject with small syringe.

—Baginski.

Aspiration of the Bladder.—In hæmaturia with formation of clots, a metal evacuator was introduced through the urethra, and forcible aspiration effected by means of a syringe. Boric acid solution was then introduced and drawn out till it returned clear several times and free from clot fragments.—Noguès.

Irritable Bladder with enuresis in young women may be cured by the faradic current with the bipolar electrode in the bladder, and the secondary current of moderate strength.—Grapow.

Phimosis.—A practical hint with regard to the treatment of phimosis, never known to fail: Use thin strips of gentian root as wedges, inserting some six or eight between the glans and prepuce. The gentian probably acts in a twofold manner, as an expanding wedge, deriving its moisture from the secretion, and also perhaps doing good as an astringent.—East.

Enlarged Prostate.—Where there is an elongated prostatic urethra, it is generally associated with a rectal tumor of large size, and the increased length of the prostatic urethra and the consequent increased perineal distance, is approximately indicated by this fact, and by measuring the distance with a catheter from the meatus to the point where urine is obtained.—Wishard.

Vulvitis in young girls is rarely caused by mechanical irritation, while one of the eruptive fevers, typhoid, eczema, or impetigo may originate it.—Comby.

The Female Urethra through the Urethroscope.—1, The mucous membrane of the canal is traversed with radial folds; 2, the urethral orifice appears in the shape of a darkish spot; 3, with regard to color, the urethral mucous membrane closely resembles the oral; 4, muciparous glands are invisible.—Ebermann.

Injection in Gonorrhœa.—

℞. Permanganate of zinc..... gram. j.
Distilled water..... " 700.

—Hertz.

Lupus.—Inject one or two drops of following into each tubercle. Ten injections can be made at a sitting:

℞. Acid. cinnamylic.,
Cocaine muriat..... āā gram 1
Spirit vini..... " 18

—Landerer.

Seborrhœal Eczema of the Lips.—Tar and sulphur, Dubreuilh; liquor potassæ as a caustic, Kaposi; scarification, Hallopeau; naphthol and yellow oxide of mercury, Brocq.

Seborrhœal Eczema of scalp, psoriasis, and favus.—

℞. Alumnol..... 0.5
Aq. dest..... 1.5
Glycerin..... 3
Lanoline pomade..... 15

—Chotzen.

Onychia is a form of disease about the nails. In its simple form it is called run round, or superficial whitlow; it occurs as a slight suppuration about the root of the nail, followed by the raising up of the epidermis; a yellow deposit of pus and abscess, which runs down along the side of the nail. The remedy is free incision; washing out; and it gets well.—Cheever.

Burns.—

℞. Anhydrous lanoline..... 10 parts.
Benzoated lard..... 20 "
Lime water..... 30 "

—Unna.

Pediculi Pubis.—

℞. Hydrargyri bichloridi..... 1
Acidi acetici diluti..... 300
Sig.: Use a lotion. This lotion not only kills the lice, but detaches the nits.

—Brocq.

Pityriasis Versicolor.—One friction with essence of turpentine will effect cure if clothing are disinfected.—Hericourt.

The Treatment of Warts.—Professor Kaposi, of Vienna (*La Semaine Médicale*, No. 52, 1893), recommends, when the warts are solitary, removal by the knife, but when multiple, and especially on the face, he employs the applications of thuya occidentalis or fuming nitric acid. Vegetations are best treated by dusting with resorcin or salicylic acid, or a plaster of ten to twenty per cent. Resorcin, if applied for a long time, acts as a caustic, and may irritate the surrounding normal skin. These same topical applications are also excellent in keratosis palmaris and plantaris, even when they are not wartlike. In multiple warts of the face he employs the following:

℞. Flowers of sulphur..... gram 20 (℥ v.)
Glycerine..... " 50 (℥ jss.)
Pure con. acetic acid..... " 10 (℥ ijss.)
Apply locally to each wart.

They dry up, become bluish, and drop off. Continue this for several days. In mollusciform nævi electrolysis is the best treatment, except when the tumors are voluminous, when the galvano-cautery or caustic may be used. —*Clinique*.

Antispasmine.—This salt is a double salicylate of narceine and soda, occurring in the form of a white powder slightly soluble in water. It is a good hypnotic and sedative. The following formula is advantageously followed:

℞. Antispasmine..... gram 1
Water of bitter almonds..... " 10
Sig.: Fifteen drops once or twice daily in sweetened water.

The remedy is especially recommended for pertussis in very young children.

Pruritus.—

℞. Acetate of lead..... gram 1
Dilute hydrocyanic acid..... " 5
Rectified spirits..... " 15
Distilled water..... " 250
Use as lotion.

Chronic Constipation.—Ewald recommends four or five grains of a combination of caffeine and chloral dissolved in water. The remedy is given by injection, and he states that he has failed only once in thirteen trials in obtaining thin stools.

Earache.—If without indications for operative treatment, drop into the ear several times daily a little of the following: Menthol and camphor, of each twenty grains in one ounce of albolene.

Correspondence.

OUR LONDON LETTER.

From our Special Correspondent.

THE SURGICAL BRADSHAW LECTURE—ASTLEY COOPER AND HIS WORK—ARE ACCOUCHEURS SURGEONS?—OBSTETRIC PHYSICIANS AND SURGEONS—MEDICAL SOCIETY OF LONDON—DR. H. R. SPENCER'S FIRST FIFTY OVARIOTOMIES—ARE THESE OPERATIONS SURGICAL OR GYNECOLOGICAL?—DEATH OF DR. EDIS, F.R.C.P.

LONDON, December 16, 1893.

I HAVE previously mentioned the Bradshaw Lecture at the College of Physicians. The surgical Bradshaw was delivered at the College of Surgeons on the 7th inst., by Sir William Maccormac, who took for a subject "Sir Astley Cooper and his Surgical Work." The life and work of this great surgeon in relation to the surgery of to-day is certainly an interesting topic, and future lecturers might well follow with semi-biographical subjects. It is more than fifty years since Sir A. Cooper went over to the majority, but his memory is still green among us. Of his surgical work your readers are competent judges—at least those of them who do not confine their attention to the work of to day, but take pleasure in tracing the progress of our art through its stages toward its actual condition. Sir A. Cooper was a careful observer and patient recorder of what he observed. His carefulness and accuracy may be judged of in his writings, and are the more remarkable when we remember the many advantages and helps we now enjoy which were not available seventy or eighty years ago. But this "Prince of Surgery," as he was called, was a man who would have shone in any sphere. A man of noble form, handsome and intellectual appearance, and courteous manners he would have won his way in other professions, but his gentleness and sympathy were eminent qualifications for the great surgeon prior to the era of anæsthetics. Of his kindness and consideration for others the stories are innumerable, and they still pass from mouth to mouth, so that the traditions of his good nature and skill are learned almost as soon as a student begins his work. So good a judge as Brodie declared that "his published works will transmit his name to posterity with those of Sydenham and Hunter as a benefactor to the human race."

Are accoucheurs physicians or surgeons? In itself the question is of little consequence, yet something hangs by the answer, viz., the further question—should abdominal operations be performed by the obstetric physicians or the surgeons of our hospitals? This question came up at the Medical Society of London on Monday, and was treated with a certain degree of acrimony. The progress of abdominal surgery has not tended to remove the jealousy with which surgeons saw ovariotomy taken from them by the so-called obstetric physicians. The latter gentlemen managed to "eat their cake and have it too," for they retained the prestige of physicians and yet performed ovariotomy and other surgical operations. Moreover, they remained in the College of Physicians, and so helped to leaven the horror with which that ancient corporation regarded the use of the knife and looked down upon midwifery. Again, these ovariotomists were assuredly specialists, and yet our ancient college keeps up its foolish prejudice against specialism; indeed its leaders never tire of fulminating against the evils of specialism, as if their own college, if composed, as they assume, of those who practised "pure medicine" and excluded surgery and midwifery, were not in reality a corporation of specialists. Howbeit the once despised men-midwives, having developed into obstetric physicians, are now proclaiming their rights to be also abdominal and not mere pelvic surgeons. Not that this is the first time the claim has been made, for I took part in the discussion raised on the point among the staff of one of our great hospitals more than twenty years ago, when one of the surgeons proposed that the obstetric men should not be allowed to use a knife, but should be restricted to scissors as a proper weapon for ladies' men. In his turn he was asked to tell his colleagues how often he had done hysterectomy.

The discussion which has led me to these remarks arose on a paper by Dr. Herbert R. Spencer, detailing his first fifty ovariotomies, and which he made a plea for the performance of this operation by obstetric physicians. Dr. Spencer succeeds Dr. John Williams as obstetric physician to University College Hospital, and claimed for that institution the gratitude of others for the example of permitting the obstetrician to operate, and yet methinks at least one hospital was equally liberal at an earlier date. Dr. Spencer urged that it is illogical for Cæsarean section—exceedingly difficult when complicated—to be left to the obstetrician and yet to deny him the right to deal with a simple ovarian cyst. If ovariotomies were divided among the surgeons to a hospital each would get very few, and Dr. Spencer thought patients would decline to come to inexperienced surgeons and go to special hospitals, and this he appeared to consider rather shocking, which, as belonging to a general hospital himself, was perhaps a natural prejudice, though he did not pretend it would be worse for the patients. In hospitals where both parties operate he had heard that the difficult cases are sent to the obstetrician and the easy ones kept by the surgeons. As teachers of obstetrics and gynecology also he claimed for his colleagues the operations in their specialty. Further, he spoke of the errors in diagnosis of surgeons who had opened the healthy pregnant uterus and asked if it is "fair that the obstetrician who can diagnose a tumor and remove it should be prevented from operating by a surgeon who is only competent to remove it." There was more in the same direction in this paper, and it naturally evoked discussion which has spread beyond the meeting.

Dr. Routh defended special hospitals from the covert attack of the paper, and held that to them belonged the credit of improved diagnosis and low mortality. He rather chaffed the surgeons with their mistakes in diagnosis, and scoffed at their "exploratory incisions" as covers for blunders. Mr. P. Gould said gynecologists owed much to surgeons—especially Lister. With the advance of abdominal surgery no doubt the diagnosis had receded. He saw an operation by a distinguished obstetrician who had diagnosed ovarian tumor and found it to be renal; on the other hand, he had operated for an obstetrician who thought the case surgical and found it to be ovarian. In either case it would have been absurd for the operator to stop and hand over the case to his colleague. Whoever opened the abdomen ought to be ready to deal with whatever he met with, and either surgeons or accoucheurs might be allowed to operate.

Dr. W. Duncan held that the art of obstetrics was surgical, and its practitioners should really be called surgeons, and he insinuated that the obstetric physicians usually had cleaner hands than the surgeons. Mr. Harrison Cripps held there was room for further division of obstetric physicians into those who operated and those who did not. Those who did should be trained as surgeons, and competent not only to open the abdomen but to deal with whatever might be found. He had felt the advantage of consultation with obstetricians who did not themselves operate. Dr. Playfair admitted that gynecology was a surgical art, but that enlightened Fellows of the College of Physicians (so some are unenlightened?) thought that obstetric physicians should be permitted to do necessary operations.

Surely this discussion shows the absurdity of our divisions, and the history of ovariotomy aptly illustrates it. "The father of ovariotomy" in England was at first a general practitioner, and became perforce a specialist. He was "Clay of Manchester," whose work was referred to by one speaker.

Let not your readers suppose the scientific aspect of Dr. Spencer's fifty ovariotomies was lost sight of by the speakers. Many noteworthy observations were made, but my available space is disposed of.

Dr. Arthur W. Edis. the eminent gynecologist, died last week after an operation for hernia. He was only fifty three years old, but last year was able to give up hospital work in order to attend to private practice only. His "Manual of Diseases of Women" must be well known to your readers, and also his various papers on obstetrics and gynecology. His remains were cremated on Monday.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

VIRCHOW'S FIFTIETH DOCTOR JUBILEE—THE SUTURES AND THEIR RELATIONS TO CEREBRAL LESIONS—METASTASES IN ACUTE INFECTIOUS DISEASES—TABES AND SYPHILIS—PROFESSOR JACOBI'S CALL TO BERLIN.

BERLIN, December 16, 1893.

MEDICAL work seemed to begin this fall with the celebration of Virchow's fiftieth anniversary as doctor. Numerous ovations were tendered and all refused save the presentation of a bouquet by the Medical Society of Berlin.

Professor v. Bergmann, as second chairman, laid special stress on the accomplishments of Virchow, emphasizing that physicians were honored socially by their standing professionally. He enumerated his more special work on pathological anatomy, ethnology, and in sanitary matters. Finally he handed Virchow a diploma as honorary president of the Medical Society and proposed three cheers, which were heartily given. Virchow responded feelingly, thanked one and all, insisted that he had always united medicine with his scientific endeavors, and that he always tried to secure for medicine that position which it really deserved. He was highly flattered at the great ovation tendered to him, in the form of an address, by the city of Wurzburg through one of his pupils, now Professor von Rindfleisch. Although he was but thirty years of age he attained great prominence in 1856, and although his politics were disliked, he was recalled to Berlin in the same year. It will be remembered that he had to leave Berlin in 1848 on account of his political antagonism to the government.

Professor Rindfleisch exhibited a skull with very pronounced sutures. He mentioned the fact that Virchow, in 1851, in a paper read at Wurzburg, demonstrated the great importance of the ossification of the sutures and their relation to the brain and its development. He pointed out that in very rare instances the brain is influenced, in most cases it is not affected at all. He showed a skull with abnormal ossification of the sutures, more especially the sagittal, lambdoidal, mastoidal, etc., although with perfectly normal brain functions, intra vitam.

Next followed a highly interesting announcement of Professor Ponfick, of Breslau, also a former pupil of Virchow, who mentioned the important literary contributions of Virchow, especially those relating to thrombosis and embolism. which, according to the old belief, were due to cell-degeneration, but now to micro-organisms. He referred in that connection to nature's efforts at elimination of poisons by the different emunctories, and alluded to the fact that in such cases we frequently find albumin in the urine. This has been regarded as a product of the bacteria acting on the epithelium of the kidney. He found, furthermore, in the course of his investigations, that the action of bacteria is frequently transmitted to the bones, and in post-mortem examinations of typhus patients he found disease of almost all the bones.

In advanced phthisis, where mixed infections take place, we find diseased bones. The milder cases may be cured, the others result in thickening of the bone remaining permanent. The animal cells destroy the vegetable cells. He then referred, in passing. to the celebration of the doctrine of the honored guest of the evening.

Until recently the healing of tuberculosis, tetanus, diphtheria, and hydrophobia was attempted by specific treatment. Recently, however, two Hamburg physicians, Eugene Fraenkel and Th. Rumpf, have attempted to cure typhus abdominalis by a specific method.

Both attempted it in different ways. Fraenkel tried the method of Brieger by using thymus and typhus bouillon cultures. From this thoroughly sterilized bouillon, which had been previously tested as to its poisonous properties on guinea-pigs, Fraenkel injected 0.5 c.c. very deep in the gluteal regions. Very little change resulted therefrom, but on the following day the dose was increased and injected on the other side. On the third day of treatment a distinct falling of the temperature was noticeable, and twenty-four hours later the temperature fell one half or even a whole degree below the temperature at which the febrile process begun. If a cure has been attained then the treatment is discontinued, if not the dose is increased 1 c.c. every second day. In this manner we can easily interrupt the fever and convert it into an intermittent variety. As soon as the remissions are attained a general improvement is manifest, profuse perspiration and diuresis occur, and the patients appear as though in a convalescent stage. The remedy does not protect against complications, nor against relapses; the latter, however, get well by the use of the same remedy.

An entirely different method was employed by Professor Rumpf. The latter had micro organisms, which had no relation to the patient, as a culture of pyocyaneus which he had developed on sterilized thymus juice. After being sure of its sterility, 0.5 c.c. was injected in the same region as of Fraenkel's culture. In some cases there was a rise of temperature following the injection. which subsided on the second day; very seldom was a reduction of temperature perceptible, but a distinct reduction occurred two days after the injection of 1 c.c., at the same time the subjective condition seemed to improve. On the fourth day of treatment patients appeared to be convalescing. To attain a cure the treatment must be continued until 6 c.c. is employed. Under this method we have results which have never previously been attained by other methods of treatment.

With this method we also have complications and relapses. The most important point which has been learnt is that we are capable of modifying and curing a disease which owes its origin to certain pathogenic germs which we recognize by micro organisms entirely foreign to the disease under consideration. Even now Sohernheim found the same condition in regard to cholera by investigations at the Bacteriological Institute of Marburg. They were able to cure guinea-pigs of cholera by injecting dead bacteria and their products.

In the last meeting of the Berlin Medical Society Professor Gerhardt read a paper on the spine in syphilis. He favored the view of those who believe tabes dorsalis and syphilis as one and the same disease etiologically considered; at least in one-half of the cases they were able to find antecedent syphilis.

In the discussion following the paper it seemed to be the general opinion that the author's views were sound. Professor Mendel found syphilis in seventy per cent. of cases of tabes. Professor Senator found syphilis also in about seventy per cent. of cases of tabes. Virchow called attention to the frequency and importance of visceral lesions in syphilis which are rarely, if ever, met with in tabes.

Finally, I desire to call your attention to something unusually interesting for Americans; that your prominent pædiatrist Professor A. Jacobi, was first mentioned and invited to fill the chair of pædiatrics recently vacant. It shows you that the great authorities which have left Europe, especially Germany, are being temptingly invited back—but we hear that, to our sorrow, he will not leave his lucrative and prominent positions in New York.

As a matter of fact, there is a distinct scarcity of pædiatrists in Germany, and we believe it will be a long time ere we can replace that most eminent of all European pædiatrists Edward Henoch.

Periostitis, when acute, permits of no delay after its nature is known. Cut to the bone at once.

RECKLESS USE OF CHLORAL.

To the Editor of the Medical Record.

Sir: Your worthy editorial in the Medical Record of December 16th was most timely and instructive.

There recently came under my care a man giving a history of chronic alcoholism, who for a period of three weeks had been in the habit of nightly taking eighty grains of chloral at a single dose. During the day he would take none.

He told me he had frequently taken as high as one hundred and twenty grains on retiring, feeling no ill-effects, but thoroughly refreshed on awakening in the morning. As the habit was rapidly gaining, he put himself under treatment.

A gradual withdrawal of the drug, substituting sulphonal for the retiring dose, putting him on large doses of strychnia, iron, etc., with occasional use of bromides, regulating his habits, and giving diversion, has thus far vanquished the habit.

F. R. Searles, M.D.

Plainfield, N. J., December 22, 1893.

TUBBING IN TYPHOID.

To the Editor of the Medical Record.

Sir: It is now more than twelve years ago since I walked along one of the busy streets of a German town with a teacher of mine—a man who has done good and lasting work in his special ways. We were returning from a lecture he had just delivered, and our ambulatory conversation had been the subject of this lecture. The Herr Professor, well pleased with himself, became personal and asked me what I thought of his lecture and the methods he had employed for inculcating the facts, etc, he had wished to force home on his hearers. I, as a student, had felt my needs better than he could think or fancy them, and I told him in what respects, from my point of view, his lecture fell short—not that it had been wanting in learning, matters of fact, good reasoning, and solid logic, and the other literary virtues a teacher has cause to be proud of, but wanting in the needs of satisfying my crying wants. The Herr Professor took my criticisms very kindly, and I was much gratified that he did so. It was one more kind act added to a hundred others for which I felt and feel deeply indebted to him. "Ah," said he, as we stopped at the corner of another street to say our "ades," "if we could only know always what you students needed to know most, how much better we could teach." Well, this episode was recalled to my mind by reading Dr. Baruch's interesting letter in to-day's Medical Record. "What an ingenious letter," said I, "and how unsatisfactory!"

The Doctor knows so much about typhoid fever and tubbing, and he wishes to convince those in doubt about the efficacy of tubbing, and yet—not forgetful of what I know about typhoid fever, besides what I have seen and heard concerning its treatment by tubbing—I am, (in spite of Dr. Baruch's letter, which seems to have been written in a jocund mood, his brains a little raised, perhaps), not convinced that tubbing is the treatment for typhoid fever under every and all circumstances. One cannot always fall into being convinced by easy methods of argumentation, and, it seems to me, Dr. Baruch has used the easiest methods imaginable just because they were nearest to hand. He speaks of the force of "rationale," and reason, and statistics in a high sounding way, as opposed to sentiment. Without sentiment civilization were impossible! In scientific medicine, it is true, sentiment is sometimes an evil, but it can be done away with in many hard though reasonable ways, and successfully. But in practice, private practice, even among the poor and needy, sentiment is not so easily annulled. Neither should it be forgotten that sentiment lets in science, even at the doors of the élite. A taking "rationale of treatment," braced up by statistics and reason, and garnished with the halo of respected and honored names, makes a fine appeal in favor of tubbing for typhoid fever. But that is not all that is needed to convince a man who may be prejudiced and misled. It would not be in good taste for me to tell such a man as Dr. Baruch would have us believe him to be, what is more essential than "rationale" "reason," "statistics," and names. It is certainly not true that "There is need of more positivism in medicine." We have positivism, and enough to spare, thrust at us every day. We want facts, but want facts and definition. Besides, in medicine as in æsthetics, bad reasoning and faulty logic are not synonymous sins. However, we may go wrong in expecting too much—even from Dr. Baruch. It was Plato who said, "Him will I call a god who can rightly divide and define." If we cannot be expected to be gods, we can, with a little effort, at any rate be modest. Dr. Baruch quotes the hospital experience of some New York and Philadelphia men, physicians whom we respect. But hospital experience is not the best guide for the demands of private practice. Statistics and experience emanating from hospitals very frequently lack definition, and in so far they are apt to be misleading. Physicians and surgeons feel themselves freer to treat disease in hospitals than they do in private practice. In private practice, necessity obliges us—the possibly prejudiced and misled practitioners—to treat the patient as well as the disease or diseases he is suffering from, and here sentiment helps as well as science and art.

From what Dr. Baruch says, one concludes that he is a lucky man, besides all else that his letter more or less impliedly claims for him; but, at the same time, one cannot suppress the query: Has he never tubbed a patient, who, after some trials, obstinately refused to be tubbed more, even preferring a bad prognosis to a promised good one, if the condition be tubbing, and yet, in spite of all, the patient get well? Cases of this kind should be brought to light, as well as such that he has quoted, although they would not look so well in a letter purposing the saving of practitioners from prejudice and error.

All the above thoughts are only a few of those suggested by the perusal of Dr. Baruch's letter, and they are not sent to your honored journal as a refutation of the contents of that letter, but merely in illustration of how one train of thoughts may start another—in short a psychological experiment that may be as interesting to others as it has been to me, and may possibly be to Dr. Baruch himself.

Very Respectfully Yours,

Adolph Rupp, M.D.

406 West Thirty-fourth Street,
December 25, 1893.

THE REAL FUNCTIONS OF A LUNACY COMMISSION.

To the Editor of the Medical Record.

Sir: From time to time in the past, efforts have been made in Michigan to create a public sentiment favorable to the appointment of a lunacy commission. The superintendents of State asylums have discussed the matter to some extent, and I think it has been conceded that in certain lines the services of a commission, or, perhaps rather, a single commissioner of high medical and legal attainments, might be extremely useful. Matters pertaining to the sufficiency of orders and the medical examinations of patients previous to their admission to an institution; the illegal or unnecessary detention of patients; the circumstances attending commitment, where conspiracy, fraud, or wrong is alleged; the investigation of complaints of patients in institutions; recommendations in respect to the commitment of patients to asylums, where the public weal is concerned, but where interested parties for one reason or another fail to act; expert services in court; investigation of questions pertaining to the property and estates of patients; attention to their legal claims when wrongfully deprived of their just rights

in legacies or bequests; the creation of a healthy public sentiment concerning hospital treatment for insanity, and the inculcation of reasonable views as to the nature of insanity itself; these, and numerous other perfectly legitimate and proper functions, might be assumed by a commission in lunacy alive to the interests of patients and the welfare of progressive psychiatry. It has never been deemed, however, by those who have felt an interest in the appointment of such a commission in Michigan that, if appointed, it would concern itself about the purchase of provisions for hospitals, or the distribution of blankets or tobacco among patients. These are subjects for the trustees and officers of individual asylums to pass upon. They are the only competent judges of the necessities of the case. It strikes an unbiassed observer that a lunacy commission is exceeding its proper limitations, that concerns itself with matters of this character.

Very respectfully,

C. B. Burr,

Medical Superintendent, Eastern Michigan Asylum, Pontiac, Mich.

New York City, December 23, 1893.

New Instruments.

A NEW SURGICAL STERILIZER.

By EDUARD BOECKMANN, M.D.,

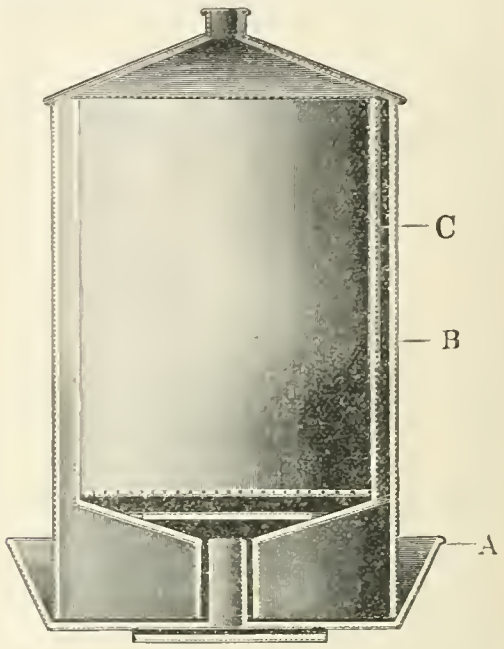
ST. PAUL, MINN.

I present to the medical profession the following sterilizer, which is the result of several years' busy and costly experimenting. It consists of three separate parts, viz.: A, the boiler; B, the cover; C, the receptacle.

The boiler has the shape of an ordinary pan, three inches deep, perforated in the centre of the bottom, where a tube, three inches long, is inserted. Underneath the bottom, at a distance of a quarter of an inch, is fastened, by aid of screws, a plate of galvanized iron.

The cover is pitched, perforated on top, where a short tube is inserted. Its depending flange is made so long that the lower rim will rest on the bottom of the boiler, when the receptacle, hereinafter mentioned, is properly inserted. The diameter of the cover is the same as that of the boiler bottom.

The receptacle has a pitched bottom, perforated at the lowest point, where a tube, three inches long, is inserted. Inside the receptacle, a little distance above the perforation, is placed a metal plate, and a little farther up a diaphragm of galvanized iron. The receptacle is provided with a loose, pitched cover, perforated and adjusted, with a short tube on top (not illustrated on cut). The diameter is one inch less than that of the cover.



With this simple apparatus we are enabled to sterilize with surgical steam (saturated, low, streaming, oversteam), with hot air, and with boiling water.

For steam sterilization the boiler is half filled with water and placed on any good fire (stove, gasolene, or gas). The receptacle is filled with articles to be sterilized and placed in the boiler, whose central tube will exactly fit inside the corresponding one on the receptacle throughout its whole length. The cover is then put on and a cork is inserted in the tube on top.

When the water boils, the steam generated will ascend between the cover and the receptacle, being prevented from escaping above by the cork and below by the water itself. The steam is forced, therefore, to work itself down through the receptacle and its contents and make its escape through the bottom perforation. Reaching the heated plate under the bottom, the steam will disappear into the air as an invisible gas (superheated steam). Steam the articles for half an hour, remove the cork, and after a short time everything inside the receptacle is perfectly dry and sterilized.

For hot-air sterilization place the apparatus on the fire without the cork in the upper tube. While the receptacle in this way will be surrounded by steam of 212° F., freely escaping through the upper tube, hot air will, as a matter of course, enter the receptacle from below. The temperature of this heated stream usually is about 400° F. when entering the receptacle, consequently scorching.

I have applied inside the metal plate, which will absorb the strong heat and again radiate it in such a manner that the temperature at the level of the wire diaphragm will register about 284° F., the necessary degree of dry heat to destroy spores in three hours.

For boiling water sterilization place the articles to be sterilized in the boiler, and adjust the cover with the cork in the upper tube.

This apparatus is made of tin or copper, and in different sizes to suit different demands. It will certainly fill a long-felt want, as its reliability is indisputable, its practicability evident, and—last, but not least—its price low.

236 East Seventh Street.

LID ELEVATOR AND EYE DOUCHE.

By E. L. OATMAN, M.D.,

NYACK, N. Y.

This lid elevator, made at my suggestion by Tiemann & Co., is in shape like the ordinary elevator, but being hollow, with open ends, it serves the additional purpose of a douche. It is of service in severe cases of purulent or gonorrhœal conjunctivitis where frequent inspection of the cornea is necessary, and its preservation dependent in

a great measure on the thoroughness with which the eye is cleansed.

When in use connect the handle of the elevator to the bag of a fountain-syringe by a few feet of rubber drainage-tubing, which, owing to its flexibility, is the best for this purpose.

Having elevated the lid and inspected the cornea, the eye may now be thoroughly irrigated, especially in the fold of transmission, which is inaccessible by ordinary methods of cleansing. The flow of the irrigating fluid is best controlled by having the nurse raise and lower the

syringe reservoir. The elevator shown in the cut is made of rubber; but if the expanded portion which enters the eye was platinum, it could be more readily sterilized after use.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 30, 1893.

	Cases	Deaths.
Typhus fever	0	0
Typhoid fever	6	4
Scarlet fever	117	7
Cerebro-spinal meningitis	0	2
Measles	292	12
Diphtheria	208	61
Small-pox	14	2
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Veterinarians and the Spoils System.—At the late Congress of the United States Veterinary Medical Association at Chicago, Dr. W. Horace Hoskins, of Philadelphia, introduced the following resolutions:

Whereas, The many rapid and uncalled-for changes recently occurring in the veterinary corps of the Bureau of Animal Industry, and the grave dangers following in their train to the true recognition and proper advancement of veterinary science, call from us an expression of opinion at this time, in congress assembled; therefore, be it

Resolved, That we deplore the degrading of this service in this department of our national Government, and in all others where the veterinarian is recognized, to the shameful basis of the "infamous spoils system," that has done so much toward hindering the proper and true growth of our country; and further, be it

Resolved, That we call upon the proper officials of our Government to rescue this service from the grave dangers now threatening the health and wealth of our nation by the appointment of incompetent, unqualified officials to enforce the wise laws provided, which have been so fruitful of good results in the past and have so well accomplished the removal of the embargoes against our food-products in the foreign nations of the world; and further,

We call upon every veterinary organization, body, society, and member of the profession to array himself against the perpetuation of this un-American, unwise, and degrading system of entrance to public service, which should be the emulation and pride of every true citizen.

The resolutions were adopted with only one dissenting voice, and Dr. Hoskins, their author, was later unanimously elected president of the Association for the coming year.

A Study of the Effects of Modern Bullet Wounds.—The chief surgeon of the Roumanian army has been making grewsome experiments with the new Männlicher rifle, with which the forces are being equipped. He placed a number of human bodies in rows, like soldiers on the field of battle. At six hundred metres five bodies were placed a half yard behind each other. A single bullet went through three bodies in succession. Upon the soft parts of the bodies the wounds were perhaps less serious than those inflicted by the old fashioned rifles, the hole made by the bullet being smaller and more even; but on the whole the injuries are far more terrible. The range of the new rifles is about two and a half miles.

Nasrol: A New Diuretic.—In a paper read at the recent session of the Society of German Naturalists and Physicians, at Nürnberg, the author expressed his opinion that digitalis and similar medicaments are not really diuretics, although they increase urinary excretion in some kinds of dropsy, by invigorating the cardiac muscle and improving circulation. Aside from certain vegetable products, and the alkaline, mercurial, and antimonial salts, di- and tri-methylated xanthine—theobromine and caffeine—are mentioned as true diuretics. However, as experience proves, their effects are not absolutely certain, because both caffeine and theobromine possess the undesirable property of contracting the blood-vessels and increasing the blood pressure, and of thus paralyzing the action upon the renal cells. Schroeder enhanced the diuretic effect of caffeine by administering with it (to increase blood-pressure) a corresponding dose of chloral hydrate (which decreases pressure and dilates the blood-vessels). This, however, did not prove to be of therapeutic value, since chloral hydrate was contra-indicated in patients suffering from kidney or heart disease. Dr. Liebrecht prepared several caffeine derivatives, such as bromo-caffeine. But this substance, it is stated, evinced, like the caffeine-chloral combination, too much of the unpleasant by effects of caffeine; and other caffeine preparations proved impracticable. Experiments with nasrol (sodium caffeine-sulphonate), however, showed that this combination did not excite the vascular nervous system; blood-pressure remained unchanged, even with doses of 0.5–1 gramme (7½–15 gr.), while urinary secretion was surprisingly increased. In one patient, who took daily 2,880 grammes (100 fl. oz.) of fluid and passed on the average 1,650 grammes (about 55 fl. oz.) a day of urine, the urinary secretion, after the ingestion of 4 grammes (1 dr.) of sodium caffeine-sulphonate, increased to 3,200–3,400 grammes (say 112 fl. oz.). In another patient, ingesting daily 3,200 grammes (106 fl. oz.) of fluid and excreting 1,700–1,800 grammes (say 60 fl. oz.), the quantity of urine, after the administration of 4 grammes (1 dr.) of lithium caffeine-sulphonate, increased to 3,600 grammes (about 120 fl. oz.). While sodium caffeine-sulphonate—nasrol proper—dissolves in water rather sparingly, the lithium and strontium salts are readily soluble; and the solvent action of the lithium is said to be greatly increased by the caffeine-sulphonic acid. The same acid is also likely to increase the diuretic action of strontium. Since solutions of sodium caffeine-sulphonate (nasrol) stronger than five per cent., do not keep long, and are of a rather bitter taste, it might be better to administer this new remedy in capsules.—*Heinz.*

Gold and Sodium Chloride in Chronic Bright's Disease.—Gold and sodium chloride, being at the same time a diuretic, diaphoretic, and alterative, the author was induced to employ it in the treatment of chronic parenchymatous nephritis, in which the skin is usually dry and the quantity of urine diminished. This treatment, it is said, always yielded excellent results, excepting in cases of far advanced or very complicated Bright's disease (hydrothorax or hydro-pericardium of long standing). The author has, in fact, employed the treatment thus far only in the idiopathic forms of chronic parenchymatous nephritis, not having had an occasion to test it in cases in which Bright's disease supervenes in the course of other affections. He administers it in 1.60 aqueous solution, giving ten to twelve drops six times daily in adults; less in children, according to age. If the renal affection is complicated with gastro-intestinal disturbances, it is advised to commence with small doses, two drops four to six times a day, the dose to be increased as the digestive functions improve. The treatment is continued until albuminuria is completely suppressed—even for months. Its effect is first felt after varying periods of time, sometimes not even for a month. It manifests itself by the re-establishment of the sudoral function, increase of diuresis, diminution and final disappearance of albumin in the urine, and disappearance of the general symptoms of Bright's disease. The improvement in the author's cases

has been so considerable that the patients have been able to resume their occupations, and have been considered cured. No recurrence has thus far supervened in these patients, it is reported. The curative action of the gold and sodium chloride being very slow, the medicament is not serviceable in cases with acute uræmic symptoms. The uræmia must first be combated by drastic purgatives (calomel and jalap), before the chloride is resorted to. As to diet, the author permits his patients mixed nourishment, provided it is sufficiently nourishing and contains many vegetable substances, which seem to exercise a favorable influence upon the metabolism in such patients. Should diarrhœa supervene, the patient is subjected to absolute milk-diet until the intestinal disturbances have entirely disappeared.—*Dowkontt, in the Medical Week.*

On the Death of a Young Physician.—Mr. William F. Lucas, of London, died recently from diphtheria contracted in the discharge of his professional work. He was a young man of great promise, who had fully equipped himself for a medical career in which great success was assured to him. His death was, however, like that of many others whom we have seen fall by the way. It illustrates the dangers of our calling and the peculiar sadness attached to the sudden removal of those for whom so much is hoped. The memory of Mr. Lucas is celebrated in a Latin poem which we print here, because it is touching and beautiful, and because it may easily be applied to some of those who have been suddenly taken from the medical and social circles of this city. We trust that many of our readers still remember enough of their early learning to appreciate the pathos of the lines. We do not ourselves pretend to determine the elegance of the Latinity.

In Memoriam.

Arbor frondibus decora,
Novis floribus odora
Ante diem cæditur.
Portu vix egressa ratis
Subita vi tempestatis
Fluctibus summergitur.

Teque magno cum dolore
Flemus in ætatis flore,
Moribus amabilem,
Acerba sorte interceptum
Tuorum oculis ereptum,
Cordibus superstitem.

Heu ! juventus animosa,
Vitaque laboriosa,
Vividum ingenium,
Sine fructu perierunt,
Nihil mores profuerunt,
Nil amor sodalium.

Verba ne edas profana,
Vita non est illi vana,
Si quis bene vixerit.
Partes suas bene gerens,
Aliisque opem ferens,
Pulchra morte concidit.

Is qui vitam sic transivit,
Plenus fide obdormivit,
Non omnino moritur.
Tutum ratis tenet portum,
Arbor in cælestem hortum
Frugifera transponitur.

The Child.—The first three years of life constitute the most important epoch of human existence. During the period from birth to the beginning of the fourth year, the special senses unfold, the moral nature develops, articulate speech and locomotion are acquired, control is gained over all the muscles, and attention, memory, comparison, imagination, generalization, judgment, and reason are gradually made manifest. The new-born infant, it must be remembered, does not start at zero, and add all these significant figures during the first three years of life. Before birth it has already existed as an individual, and been subjected to many influences as yet imperfectly understood. Whatever their development, the germ of human faculties is in every new-born child. The organized human being lives and develops conformably to its hereditary pre-dispositions, to its natural individual constitution, and to its environment. "At birth the gate of gifts is forever closed." The difference between the faculties of a little child and those of a grown person is quantitative rather than qualitative. As human personality and human power are roughly blocked out during antenatal days, what then remains for education to do? What part of the human creature is most susceptible to the influence of training and surroundings? It is the moral sense that is the inherited faculty most susceptible to the influence of education and to individual culture. Race culture does not insure personal morality. It is a special, definite, individual thing, and must be awakened and trained in each child separately.

As material prosperity is the basis of all civilized morality, the first thing to do is to find out what constitutes the material prosperity of childhood. Hygiene, in its widest sense, covers the whole ground. Plenty of sleep, fresh air, and sunshine, physical exercise out of doors, proper food, warm clothing of light weight that is not too fine for games and romps, companionship of other children of the same age, the training of the senses, and the formation of habits conducive to law and order, may be said to be the material prosperity of childhood, that constitutes the basis of a morality sufficient to meet and surmount the shocks of a lifetime. This hygiene or material prosperity of childhood is pleasantly and practically treated, in the simplest manner possible, in a little book called "The Child," by Bertha Meyer. While it contains much that everybody knows, it also contains valuable suggestions not in the common stock of knowledge. The absence of all technicalities is an advantage to the average mother, who naturally prefers thoughtful advice to the senseless traditions of Mesdames Brown, Jones, and Robinson. "Life is bounded by physical conditions," says the author. "The body contains all the elements that are necessary for the development and forming of the mind." Disease and suffering in infancy and childhood prevent the mind from attaining the full development and exercise of its powers. The strong body in infancy renders the future reasonably secure. And ten chapters are devoted to directions concerning ventilation, exercise, food, the forming of good habits, the cultivation of the æsthetic sense, the sharing of happiness and responsibility by children and parents, together with some account of German philanthropy that has for its end the amelioration of childhood among the poor. There is a plea for the largest liberty in the nursery and for unrestrained intercourse with nature, for frolicking out of doors, for regular tasks, and for the full development of the left hand, for justice and simplicity, for the training of the senses, that later all inharmonies of form, sound, and color, and all noxious odors may be avoided, and the sensible advice is given that a physician should always be called in to inspect any rash that may appear upon a child's body, or to pronounce upon any unusual condition of the limbs or trunk. "The Child" cannot fail to be a comfort to the ignorant yet loving mother, whose name is legion.

Slow Promotion.—Kaposi and Neumann, after twenty-seven and thirty-two years of service respectively in the University of Vienna, have been made ordinary professors of dermatology.

A Grim View of It.—The death of an ossified man in Tennessee is reported. He died hard.—*Chicago Tribune.* [This is as bad as the man who swallowed a thermometer and died by degrees; it suggests also the case of the consumptive undertaker who died of a coffin.]

Chance or Chancre.—The *Pittsburgh Medical Review* makes Jonathan Hutchinson say, in speaking of the beauties of circumcision: "I have never seen cancer of the penis in a Jew, and chances are rare." Does it mean that the learned gentleman has few opportunities of observing the condition, or that Hebrews have few chances of acquiring it?

A FOURTH CASE OF AMPUTATION AT THE HIP JOINT BY THE AUTHOR'S BLOODLESS METHOD.

BY JOHN A. WYETH, M.D.,

NEW YORK.

PROFESSOR OF SURGERY AT THE NEW YORK POLYCLINIC; SURGEON TO MOUNT SINAI HOSPITAL.

W. M. F—— came under my care through the courtesy of Dr. O. I. Halbert, of Waco, Tex., in February, 1891. He was then twenty-five years old, with a history of "hip disease" since his fourth year of life. The left lower extremity was much smaller in development than the right, and shorter by about five inches. The femur was adducted about fifteen degrees and flexed on the abdomen to about sixty degrees, and was immovably anchylosed with the pelvis. There were ten or twelve openings scattered over an area of a foot in diameter, on the trochanteric surface of the thigh, in the groin, and over the sacrum and rim of the ilium. He was waxy in appearance, much "run down," and evidently anæmic from prolonged sepsis. The diagnosis was chronic hip disease (tuberculous osteo-arthritis) with involvement of the bones of the pelvis in the vicinity of the acetabulum.

In February, 1891, under ether, I incised these sinuses, curetted with Volkmann's spoon, and introduced drainage tubes in various directions. One tube entered near the anterior superior spine of the ilium, passed by the acetabulum, and emerged near the anus. This thorough drainage, with frequent irrigation with sublimate solution, 1 to 5,000, brought about considerable improvement in his general condition. I advised him to return home and come to me whenever the drainage was not efficient.

This he did in November, 1893, and on the 20th of this month, having satisfied myself that a cure could never be effected without removing the useless limb and thus enabling me to reach the diseased bones, I amputated by the bloodless method. By reason of the anchylosis and malposition of the hip the amputation was more difficult than usual. I could not break the femur loose from the adhesion to the pelvis, and was compelled to chisel it away. *This was done, and all vessels secured with the tubing constrictor or tourniquet still in situ.* Silkworm gut sutures were inserted, the wound packed with warm sterilized gauze, and the sutures partly tightened over this packing. There was no hemorrhage except that which oozed from the chiselled bony surfaces. The patient rallied without a symptom of shock. Forty-eight hours later the dressing was changed, the temporary packing removed, and the sutures finally tightened. The patient recovered, and was out on crutches at the end of the third week. The operation lasted forty minutes.

As set forth in a recent paper read before the New York State Medical Association, and published in the *Medical News* of December 9, 1893, I have, as a result of the experience of other operators and myself, improved upon the technique of this operation, as given in the earlier publications. Under strict antisepsis it is as follows:

1. With the patient in the usual position for a hip-joint amputation, the limb should be emptied of blood either by elevation of the foot and lowering of the trunk, or by the Esmarch bandage applied from the toes to the trunk. Under certain conditions the bandage can be only partially, or may be, not at all, applied. When a tumor exists, or when septic infiltration is present, pressure should only be exercised not quite to the diseased portion for fear of driving septic matter into the vessels. After injuries attended with great destruction, crushing, or pulpification, of course the Esmarch bandage is not applicable, and one must trust to elevation to save as much blood as possible.

2. While the member is elevated, or before the Esmarch bandage is removed, the rubber-tubing constriction is applied.

The object of this constriction—and it is the chief point in the method—*is the absolute occlusion of every vessel at the level of the hip joint safely above the field of operation, permitting the disarticulation to be completed and the vessels secured before the tourniquet is removed.*

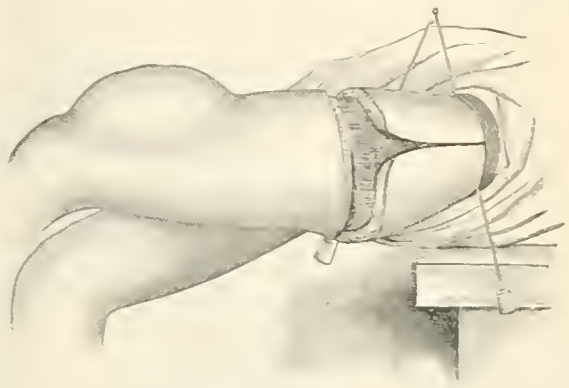

FIG. 1.—The needles and constrictor applied. Circular and longitudinal incisions for skin-flap.

To prevent any possibility of the tourniquet slipping I employ two large mattress-needles or skewers, about three-sixteenths of an inch in diameter and ten inches long, one of which is introduced one inch below the anterior superior spine of the ilium and slightly to the inner side of this prominence, and is made to traverse superficially the muscles and fascia on the outer side of the hip, emerging on a level with, and about three inches from, the point of entrance.

The point of the second needle is made to enter one inch below the level of the crotch internally to the saphenous opening, and, passing squarely through the adductors, comes out an inch below the tuber ischii. The points are at once shielded by bits of cork to prevent injury to the hands of the operator. No vessels are endangered by these skewers. A piece of strong, white-rubber tube, half an inch in diameter and long enough when tightened in position to go five or six times around the thigh, is now wound very tightly around and above the fixation needles and tied. If the Esmarch bandage has been employed, it is now removed. Dr. Lanphear succeeded in holding the construction in place with only one (the outer) needle. Dr. Deaver was equally successful in holding the tubing well up by two strips of roller bandage, one before and one behind, held by an assistant, and thus dispensing with the needles. Since the needles are, however, absolutely safe, easy to obtain, and inexpensive (a piece of telegraph wire, even, will suffice) and entirely out of the way, I do not see any benefit to be derived from their disuse. On the contrary, I should be afraid to operate without them.

3. In the formation of flaps the surgeon must be guided

by the condition of the parts within the field of operation. When permissible the following method seems ideal:[1] About six inches below the tourniquet a circular incision is made, and this is joined by a longitudinal incision commencing at the tourniquet and passing over the trochanter major. A cuff that includes the subcutaneous tissues down to the deep fascia is dissected off to near the level of the trochanter minor. At about the level of the trochanter minor the remaining soft parts, together with the vessels, are divided down to the bone by a circular cut, and, in order to facilitate the search for the vessels, the soft parts are rapidly removed from the femur for several inches below the line of the divided muscles. At this stage of the operation the larger vessels, veins as well as arteries, should be tied with good-sized

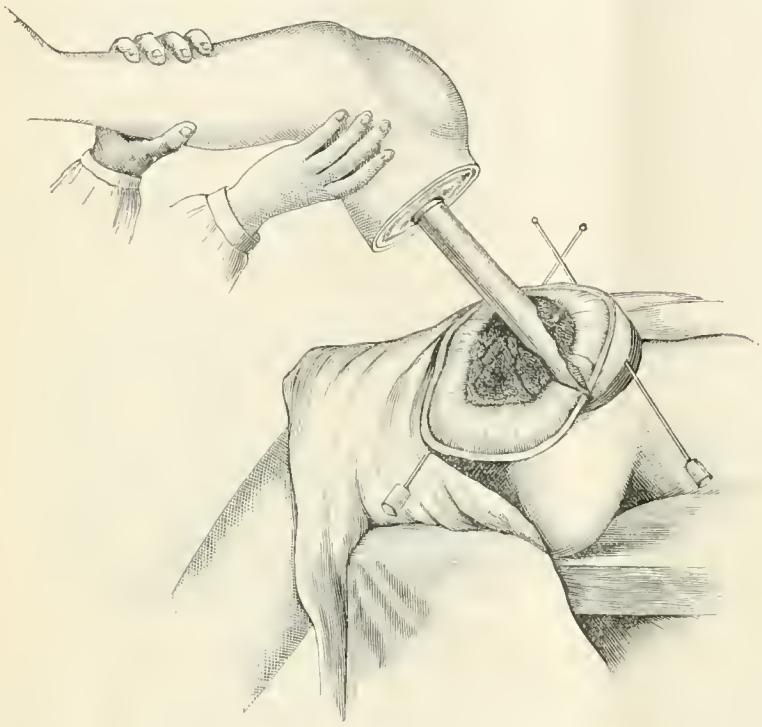

FIG. 2.—Cuff of skin and subcutaneous fat turned back, muscles divided at level of small trochanter, bone partly stripped, and large vessels exposed for deligation.

catgut.[2] As suggested by Professor Murdoch, of Pittsburg, I now leave the entire extremity intact and use the full length of the limb as a lever in dislodging the head of the bone.

When the larger and easily recognized vessels have been secured, the muscular attachments to the upper extremity of the bone are lifted off with scissors or knife, keeping along very close to the bone. Holding the soft parts away with retractors, the capsular ligament is exposed and divided in its circumference. Forcible elevation, abduction and adduction of the thigh permit the entrance of air into the socket, and, at the same time, rupture the ligamentum teres, and the disarticulation is thus easily and rapidly effected.

Properly conducted up to this point, not a drop of blood has escaped, except that which was in the limb below the constrictor when this was applied. If now the tourniquet be carefully and gradually loosened each bleeding-point may be determined and the forceps applied as required until the tube is entirely removed.

Should any difficulty be encountered in the effort at enucleation (which is scarcely possible), the same precaution in securing all bleeding points should be exercised in removing the tourniquet, and enucleation completed with the tourniquet out of the way.

4. There remains the closure of the wound, with the usual precaution of drainage. I prefer silkworm-gut for suture material, and one good-sized rubber drain from the acetabulum out at the most dependant part of the wound.

When by reason of the proximity of a neoplasm or the destruction of the parts by accident or disease, this ideal method is not practicable, any modification may be practised, preference being given to the incision that keeps furthest from the tumor or gives the healthiest flaps. When there is not sufficient material for perfect closure it is even safer to err on the side of an unclosed wound and trust to granulations or grafting for ultimate closing of the wound.

Before concluding the consideration of the technique I wish to emphasize a point of great importance. When, by reason of severe hemorrhage before operation, or when from any pathologic anæmia or condition of weakness, the operation should be rapidly completed and the small amount of blood that will necessarily be lost from capillary oozing should be saved, suturing of silkworm-gut should be rapidly introduced, the wound packed with hot sterilized plain gauze (not iodoform or bichloride gauze), and the sutures temporarily tightened for snug compression of the wounded surfaces. This packing at once controls all oozing and can be removed, and in from twenty-four to forty-eight hours after reaction the sutures finally secured.

The case herewith reported, with an additional successful case performed by Professor J. M. Holloway, of Louisville, for sarcoma, just made known to me by private communication, make a total of 42 cases by this method, with 9 deaths, a death-rate of 21.4 per cent., as against Ashhurst's table of 633 cases in which the total death-rate was 64.1 per cent.

NOTE.—In the issue of the MEDICAL RECORD of December 16, 1893, Dr. W. H. Buechner, in writing of Amputation at the Hip-joint, remarks: "The Volkmann operation, of which Wyeth's is a modification," etc. I was not aware, until I read this, that the great surgeon, Volkmann, had ever done an operation at the hip of which mine was a modification. So far in the German literature at my command I have failed to find any reference to it. In the *Deutsche Klinik* for 1868 are three hip-joint amputations by Volkmann, but in each of these a preliminary deligation of the femoral was done. Dr. Billroth and Luecke, *Deutsche Chirurgie;* Von Pitha and Billroth, *Handbuch der Chirurgie;* nor in the works of Koenig, Linhart, Heinecke, or Esmarch, nor in *Centralblatt für Chirurgie* or *Klinische Vorträge*, of which Volkmann was an editor, can I find any description or mention of any such operation. My operation, as originally brought out, is a modification of an American operation by Dr. Walter Brashear, done at Bardstown, Ky., in 1806, before Volkmann was born. He placed his tourniquet high up, amputated the thigh well below, tied all the vessels, and then made a longitudinal incision over the trochanter and remainder of the femur, and disarticulated. When I did my first three hip-amputations I did not know of the Brashear or any other similar procedure, but I am proud to discover that a Southerner and American was the pioneer in this method which has been claimed for Dieffenbach and other foreigners. My bloodless method as perfected permits the use of this old circular and longitudinal incision or any other method of forming flaps.

[1] At Bardstown, Ky., in August, 1806, Dr. Walter Brashear amputated at the hip, in a negro lad, seventeen years old, on account of a severe fracture of the femur and laceration of the soft parts. A circular incision was made, the muscles divided well below the hip-joint, and the vessels secured as the operation progressed. Then a longitudinal incision along the outer side of the limb exposed the remainder of the bone, which, being freed from its muscular attachments, was disarticulated at the socket (Professor D. W. Yandell, in American Practitioner and News, 1890). Dieffenbach's name has been prominently associated with this operation among surgeons, but Dieffenbach did not take his degree in medicine until 1822, sixteen years after the pioneer Kentuckian had performed his operation, the first hip-joint amputation performed in the United States.

[2] I employ catgut in all cases and have never had a secondary hemorrhage.

The claim I insist upon is this: *with the two needles properly inserted the elastic cord occludes every vessel at the level of the joint and permits the complete disarticulation with the tourniquet still in place.* No compression over the pelvic or abdominal regions is required. No tissue or organ is endangered. This method is original, and, I believe, novel. I honor Richard Volkmann above most surgeons, for his great work ended too soon for the good of science, but I cannot give him credit for what an American surgeon did.

OPERATIVE SURGERY OF THE GALL-TRACTS, WITH ORIGINAL REPORT OF SEVENTEEN SUCCESSFUL CHOLECYSTENTEROSTOMIES BY MEANS OF THE ANASTOMOSIS BUTTON.

By JOHN B. MURPHY, M.D.,

CHICAGO, ILL.

PROFESSOR OF SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS; PROFESSOR OF SURGERY, POST-GRADUATE SCHOOL AND HOSPITAL; ATTENDING SURGEON, COOK COUNTY HOSPITAL; ATTENDING SURGEON, ALEXIAN BROTHERS' HOSPITAL; CONSULTING SURGEON TO HOSPITAL FOR DESTITUTE CRIPPLED CHILDREN; VICE-PRESIDENT OF NATIONAL ASSOCIATION OF RAILWAY SURGEONS, ETC.

Of the many absorbing topics of medical literature, of the many changes in the art of surgical treatment made in the last two decades, of the many glorious achievements attained in this period under aseptic and antiseptic methods, of these in which the results are still imperfect and offer great reward for honest experimental and clinical research, one of the youngest, and yet a very interesting and inviting one, is the surgery of the gall-tracts. All of its achievements are the fruit of very little over a decade of labor; and probably we have only just begun to make progress in this direction. Great possibilities are before us. In drawing your attention to this subject to-day, it is not my desire so much to enumerate the steps already accomplished, as it is to ask your assistance for its further advancement. The scope of this paper only includes the operative element of the surgery of the gall-tracts; I will therefore not go into details as to the lesions which produce the necessity for the operation, but will only refer to them cursorily, as indications for the special operation to be performed. We will first devote a few minutes to the surgical anatomy of the region in which they are situated, as well as to the tracts themselves. Second, we will consider the functions or physiology of the gall-bladder and gall-tracts; for good surgery is based on good physiological principles, and good operations must be executed on good anatomical lines. Third, we will take up the individual operations and the special indications for each.

The Gall-bladder.—The fundus of this organ lies opposite the ninth costal cartilage, close to the outer edge of the rectus; the body itself is situated in a fossa on the under surface of the right lobe of the liver, having the quadrate lobe to its left. It is in immediate contact with the hepatic flexure of the colon and the first portion of the duodenum. The gall bladder is of pyriform outline, and when full is seen projecting beyond the anterior border of the liver, coming in contact with the abdominal wall at the cartilage of the ninth rib. It extends almost directly backward, deviating only a little to the right and upward; it measures from two and a half to four inches in length, and one and a half inch in diameter at the widest part, and holds about one fluid ounce. It is always found full, except where some external pressure is brought to bear upon it. It is attached to the liver by connective tissue, the lower surface is covered by peritoneum, though occasionally it entirely surrounds the viscus and forms a sort of mesentery to attach it to the liver. The neck of the gall-bladder gradually contracts until it forms the cystic duct. This duct is a tube, an inch to an inch and a half long, which connects the neck of the gall bladder with the hepatic duct, and both combine to form the common duct, or the ductus communis choledochus. The cystic duct is directed backward and to the left as it runs in the lesser omentum; the hepatic artery being to the left and the portal vein behind. The hepatic artery passes behind the hepatic duct and between it and the portal vein. This is a very important point to remember, as it assists the operator in differentiating between the duct and the vein in operations. The duct and vein both having the same color, and being situated in close proximity, it is very important to recognize the duct in this situation above the ar-

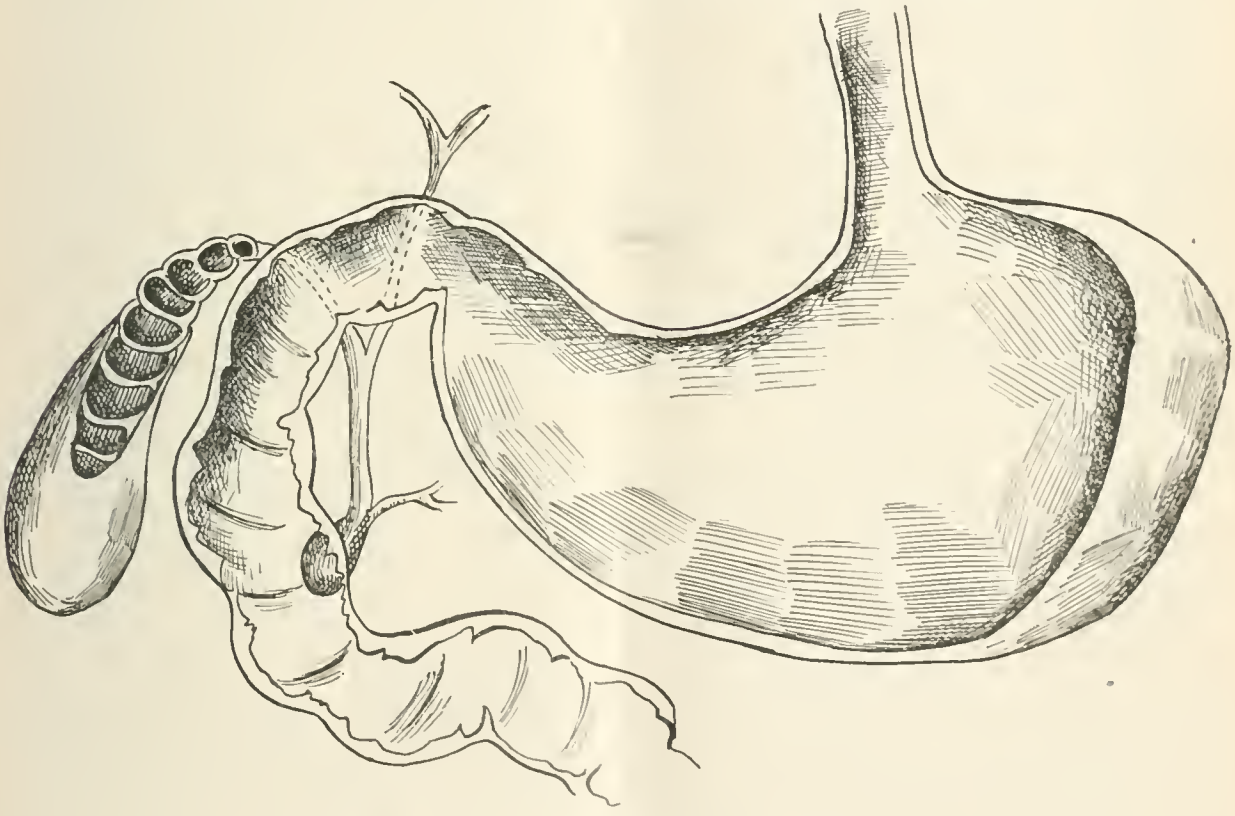

Fig. 1.

tery, and the vein below it. The hepatic duct is formed by a branch from each lobe of the liver in the transverse fissure, and is directed downward and to the right in the lesser omentum, the hepatic artery being to the left at its first part, and then behind. It is not quite two inches long, and joins with the cystic duct to form the common duct. The common bile duct is about three inches in length: it passes down between the layers of the lesser omentum, immediately in front of the portal vein, and to the right of the hepatic artery; it then passes behind the first part of the duodenum, then between the second part and the head of the pancreas, and ends at the lower part of the second segment of the duodenum by opening into that part of the intestine, on its left side and somewhat behind. It pierces the intestinal wall very obliquely, running between the muscular layers for about three-fourths of an inch. The pancreatic duct enters the common duct just before its termination. Immediately below, where the pancreatic duct opens into the common duct, there is a dilatation of the common duct, called the ampulla of Vater. There is a slight constriction at the terminus of the duct, the papilla. This papilla in the duodenum is about four inches from the pylorus. The common duct has a diameter of two lines, its width at the ampulla is three lines; it is narrowest at its outlet into the duodenum. The cystic and hepatic ducts are a little narrower than the common duct. The diameter of the ducts is a matter of considerable practical importance; that of the cysticus and choledochus being so near alike that a concrement that will produce obstruction in the former will do the same in the latter, though of a lesser degree, until it reaches the ampulla, where there is considerable more space. Stones are frequently retained in the ampulla, as the orifice of the duct in the intestine is much smaller than any portion of the tract. Calculi retained in this position, buried behind the duodenum, produce very grave symptoms, as jaundice, and a septic fever of a typical intermittent character.[1] Obstruction at this point, on account of its location, is so very difficult to reach and remove that the surgeon, in place of attacking the obstacle producing the obstruction, selects a method of circumventing it, and allows the bile to enter the duodenum through another tract, viz., by cholecystenterostomy. It will be seen that the distance from the fundus of the gall-bladder to the opening of the duct in the duodenum, is made up of the combined lengths of the gall bladder, ductus cysticus, and choledochus, measuring in all from six and a half to eight and a half inches. This should be remembered in sounding the ducts for obstructions with a bougie or probe. The gall-bladder consists of three coats, the serous, the fibrous and muscular, and mucous. The serous coat covers only about two-fifths of its surface, that on its under side. The mucous coat is raised in rugæ, bounding polygonal spaces, which are largest about the body. (These rugæ play an important part in the formation of hepatic calculi.) The mucous membrane is lined with columnar epithelium, and contains many mucous glands. At the neck the mucous membrane forms folds projecting into the interior, acting as valves (Heister's). This layer contains an anastomosis of blood-vessels and a fine plexus of lymphatics (the presence of these lymphatics accounts for the formation of secondary abscesses and septic manifestations from infective lesions of the gall-bladder). The fibrous and muscular coat consists more of fibrous than muscular tissue, and has but very little power of contraction, since I found in the healthy gall-bladder of the dog, by ligating the ductus cysticus, that only a small quantity of bile (average thirty drops) was forced out by the automatic contraction of the gall-bladder through a cannula placed in its wall; this quantity representing only about six per cent. of the contents of the gall bladder.

Physiology.—This leads us to a consideration of the physiology of the gall-bladder. The gall bladder is credited by physiologists with being the storehouse for the bile. Landois states that "the gall is secreted continually, but part is stored in the gall-bladder, and poured out copiously during digestion." This expresses the accepted theory of the functions of the gall-bladder. I desire to question the correctness of this theory, and in order to place the issue more clearly before you, make the assertions, bold as they may seen, first, that the gall-bladder is not for the purpose of storing the bile and delivering it into the intestines on demand; second, the gall-bladder is the controller or governor of tension of the bile circulation. When we consider that the amount of bile secreted daily is 40 ounces (Murchison), 566 grammes (Westphalen), or 652 cubic centimetres (John Ranke); or about 105 minims to each pound of body-weight; we can readily see what little difference it would make in the quantity and current of bile entering the intestines at the time of digestion, even if the gall-bladder should contract and empty its whole contents, one ounce, into the intestine during the period of two hours of time, *i.e.*, the two hours between three and five hours after the ingestion of a meal. For instance, the bile flows most rapidly at two periods, viz., between three and five hours, and between eleven and thirteen hours, after the ingestion of food; in those two periods about ten ounces of bile is discharged. If the quantity of bile forced out of the gall-bladder by its inherent contraction, one-half drachm, be added or taken from this ten ounces, would it make any perceptible difference in the current? It can be readily seen that it would make no appreciable difference in the whole quantity discharged, *i.e.*, ten ounces. We are then forced to the conclusion that the liver secretes at these periods this large quantity, and that it is not "poured out" by the gall-bladder as stated by Landois. Again, if the function of the gall-bladder were to contract and expel its contents during the act of digestion, would we not frequently find an empty and physiologically contracted gall-bladder, either ante-mortem or post-mortem? I have yet to find one, notwithstanding I have observed them on the living and dead subjects, at all hours before and after eating; and I have yet to learn of a surgeon who has found a physiologically empty gall-bladder. That the gall-bladder does not empty and fill with each digestive act, is further supported by the fact that the bile in the healthy gall-bladder is of much greater specific gravity than that in the hepatic, cystic, and common ducts of the same subject. The bile in the cystic duct is like the bile in the hepatic and common ducts, and differs from that in the fundus of the gall-bladder. If the gall-bladder emptied and filled with bile several times in each twenty-four hours, *i.e.*, after each meal, the bile should have the same specific gravity as the bile in the cystic duct, which is not the case. Further, the bile in the cystic duct has the same specific gravity as that in the hepatic and common ducts, which shows that only this small quantity changes with the contraction and dilatation of the gall-bladder. This degree of contraction and expansion is very limited, depending upon the degree of tension of the bile circulation. After ligation of the cystic duct at its junction with the gall-bladder, and extirpation of the latter, it has been found that in a number of months the cystic duct becomes much dilated, resembling a miniature gall-bladder (Oddi). I have verified this by one experiment.

Experiment III. May 14, 1892.—Dog, male; weight, thirty-five pounds; cholecystectomy; silkworm gut ligature of adhesions to liver; subsequent section; silkworm gut ligature of ductus cysticus top sewing peritoneum. The dog was sick for the first forty eight hours, after that he rapidly improved, and in four days he was apparently as well as ever. No jaundice.

June 12th.—The dog has become very fat and is the most playful dog in the laboratory.

August 31st.—Dog killed. The cystic duct was found to be dilated to a globular sac, five-eighths of an inch in diameter.

After a gall-bladder and intestinal fistula has been established, gradual contraction occurs; the gall-bladder contracts to a tube not much larger than the cystic duct,

[1] See Dr. W. E. Quine's excellent monograph on this subject.

as the element of tension is here entirely removed. This change requires several weeks. I do not know that dilatation of the cystic duct after cholecystectomy has been observed in man; it is possible that it does not occur, since in man there is no sphincter muscle at the opening of the common duct into the intestine, as in the dog. The tension theory of the gall-bladder is further supported by the mechanical relations of the gall-bladder and cystic duct to the hepatic and common ducts. It will be noticed that they occupy the same relative position to the current of bile passing along the hepatic and the common ducts, that the air-chamber in the fire engine does to the stream of water flowing from the pump to the hose. The elasticity of air in the small air-chamber contributes greatly toward producing a continuous instead of a pulsating stream, as would occur with the strokes of the piston were there no elastic chamber. In place of the air, in the case of the gall-bladder we have the elasticity of the walls of the viscus itself, which keeps up the continuous pressure by its expansion and contraction, and thus acts as a tension controller of the bile circulation. It performs the same function as the second bulb in an atomizer in regulating the uniformity of the spray. The gall-bladder is congenitally absent in a considerable number of animals and men, and its absence appears to have no appreciable effect on the health of the organism. I have gone into the details of this somewhat thoroughly, because a clear understanding of the physiological principles is necessary in order that we may better judge the most desirable operations to be performed under given circumstances.

The various pathological conditions of the gall-tracts which necessitate operative interference requiring laparotomy, to which line of operations this paper will be confined, I will only mention by name, and will not go into the details of each. In the order of frequency with which they produce disturbances they should be classified as follows:

1. Cholelithiasis, gall-stones: *a*, in the gall-bladder; *b*, in the ductus choledochus; *c*, in the ductus cysticus; *d*, in the ductus hepaticus; *e*, in the diverticula; *f*, ulcerative perforation into the peritoneal cavity. 2. Cholecystitis, empyema, hydrops. 3. Cancer of the pancreas. 4. Neoplasms involving the ducts. 5. Carcinoma of the gall-bladder. 6. Traumatism.

Operations.—The operations on the gall-tracts after the abdomen has been opened will be divided into ten classes, viz.:

1. Puncture of the gall-bladder.
2. Incision into the gall-bladder without further operative procedure.
3. Suture of the gall-bladder to the abdominal wall with secondary incision (cholecystostomy, two sittings).
4. Suture of the gall-bladder in the abdominal wall with immediate incision (cholecystostomy, one sitting).
5. Incision of the gall-bladder, removing its contents, immediate suture of the gall-bladder, and suturing it in the wound of the abdomen (cholecystotomy).
6. Incision of the gall-bladder with immediate suture and reposition in the abdomen (cholecystendysis, ideal cholecystotomy).
7. Cholecystenterostomy, gall-bladder, and intestinal fistula.
8. Cholecystectomy. Removal or amputation of the gall-bladder.
9. Choledocho-lithotripsy, or crushing of gall stones in choledochus.
10. Choledocho-lithectomy, with subsequent suture of duct.

Individual Operations.—1. *Puncture of the Gall-bladder.*—The puncture of non-adherent gall-bladder after opening the abdomen has been performed but a very limited number of times (twenty-five), and through error in diagnosis in the greater number of cases. Eight times the operation was performed for its therapeutic effect, after the abdomen had been opened. Four of these eight were supposed to be circumscribed hydrops of the peritoneum; two of these cases terminated fatally. In the other four the diagnosis was clear, and the object of treatment was to relieve the patient by aspirating the gall-bladder. The cause of the dilatation was in three cancer of the pancreas, in one it was due to calculus in the cystic duct. The final outcome in one case was unknown, one of the cases died of exhaustion after repeated puncture; in the other two cases cholecystotomy was performed; one of the two died. We have here, then, a fatality of twenty-five per cent. from simple puncture of the non-adherent gall-bladder. In the other seventeen cases the puncture was purely explorative. Puncture of the gall-bladder from the surface of the abdomen, without incision, was suggested by G. Harley, for the purpose of sounding for gall-stones. He pronounced it an easy and safe method for sounding for impacted stones, but his patient died twenty-four hours after the operation, of "enteritis and peritonitis." This operation is to be condemned, first, because there is great doubt that a diagnosis can be made with a needle, even if a stone is present. Second, a needle puncture of the gall-bladder is dangerous because the opening remains patulous (as I have frequently seen following aspiration preparatory to insertion of the button), from an absence of, or very limited, contractile power of the tissues of the wall of the gall-bladder, and from tension by the bile pressure within. Third, if the contents of the gall-bladder in the case should be septic, we would have as a result a septic peritonitis. Courvoisier says, "that a surgeon should even hesitate to aspirate a case where the diagnosis of gall-bladder lesions was even suspicious, and never except where no other means of diagnosis is left, a laparotomy being a much more rational and safe method."

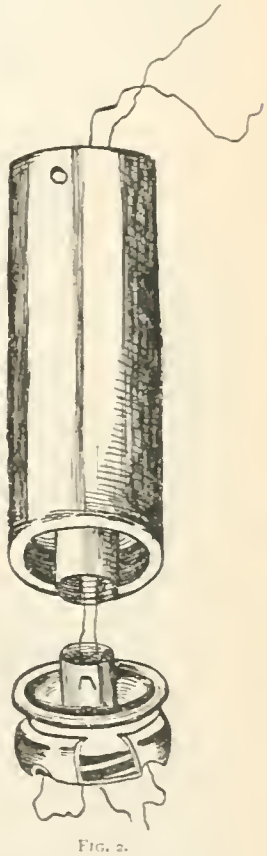

Fig. 2.

2. *Incision of the Gall-bladder Without Further Operative Procedure.*—This operation is performed for, and should be limited to, cases where the gall-bladder, on account of gangrene of its wall or extensive adhesions all around it, render it impossible to either suture it to the abdominal wall or approximate it to any portion of the intestinal tract, and where it is compulsory to secure drainage of the bladder, or to use the bladder as a canal to allow the escape of bile in obstructive jaundice that jeopardizes the life of the patient. A drainage-tube may be inserted in the incision of the gall-bladder and packed around with gauze (Maurice H. Richardson), the omentum drawn about it in a few sutures to prevent the fluid passing into the peritoneal cavity, or what is still better, my method of insertion of a "button tube drainage" of the pattern I here present. This has the advantage: 1, That it can be easily and rapidly inserted deep in the abdominal cavity, though the gall-bladder may be very much contracted: 2, that it prevents with certainty the contact of the gall-bladder contents with the abdominal viscera until such time as adhesions have formed around the tube; and 3, that it leaves a large opening, when the instrument is withdrawn from the gall-bladder, through which calculi may be extracted. The operation with the "button tube" is performed as follows: An incision is made in the abdominal wall in the usual position for operations on the gall-bladder, beginning at the ninth costal cartilage, parallel to the external border of the rectus

muscle for a distance of two and a half inches. The gall-bladder is located, a sufficient surface of its wall exposed, the contents aspirated, the purse-string suture inserted, the gall-bladder incised, male half of button inserted, purse-string tied and cut short; the tubular portion of the button is then pressed into position; the tube is then drawn out as far as the gall bladder will permit, and held there with a pin passed through the openings in the side. During the time the pressure atrophy in the portion of the gall-bladder clasped between the button is taking place, a cicatricial wall is being formed about the tube which acts as the walls of a sinus after its production, and insures continued protection to the peritoneal cavity.

The following operation was performed: Mrs. K——, aged thirty five; several children. This case was referred to me by Dr. J. H. Hoelscher, who furnished the following history: Four years ago the patient was first attacked with severe pain in the region of the gall-bladder, which was soon followed by nausea and vomiting. This pain lasted several hours, and a few days after the onset the patient became very much jaundiced. Tenderness continued over the gall-bladder for ten days or more after the attack. These attacks occurred at frequent intervals during the past four years; after some of the attacks she passed gall-stones, and has a collection of them on hand. About two years ago she had one very severe attack, lasting much longer than the others and accompanied by more pain, fever, and tenderness. It took her a long time to rally from this attack. The last attack, ten days before operation, was followed by jaundice and a few stones were passed. Not more than half of the attacks were followed by jaundice. She suffered very much most of the time from digestive disturbances and a constant aching in the side.

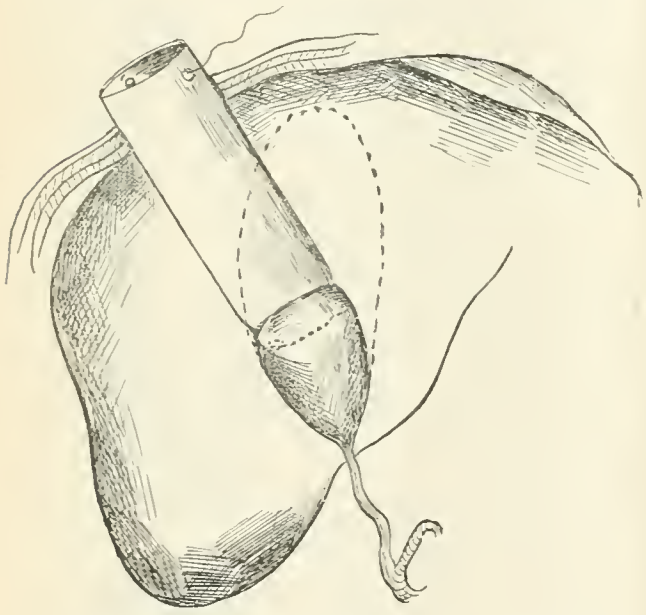

Fig. 3.

Present Condition.—Patient a well-nourished, stout, healthy-looking individual. On examination we find a large sensitive tumor extending down about three inches below the right ninth costal cartilage. This tumor can be felt separate and distinct from the kidney, and presses against the abdominal wall in front. It moves synchronously with the diaphragm in respiration.

Diagnosis.—Cholelithiasis with pericystitis. Operation by Dr. Murphy, assisted by Drs. Hoelscher and Lee. Present, Dr. J. McFadden Gaston, of Atlanta; Dr Quinby, of Jersey; Drs. Cole and Owings, of Montana; Dr. Jelks, of Hot Springs; Drs. Wittwer, Hartmann, E H. Lee, Conley, and Oswald. The usual incision was made at outer border of rectus. The gall-bladder was completely surrounded by adhesions and contracted; it was impossible to approximate it to the abdominal wall or to any portion of the bowel. It was decided to put in the drainage button-tube. A portion of the fundus of the gall-bladder was exposed sufficiently large to insert the button and to place it in position. A number of calculi were removed and many allowed to remain. The tube projected above the wall of the abdomen, and the wound outside was packed with iodoform gauze. The button-tube liberated itself on the seventh day and a number of stones followed. The patient made an uninterrupted recovery and is now in excellent health: has a small sinus, but no bile is escaping (August 20, 1893). Sinus closed September 15, 1893.

Case II.—Mrs. M——, aged fifty, Indianola, Neb.

Diagnosis.—Cholelithiasis, impaction in choledochus. Had had repeated attacks of gall-stone colic accompanied by jaundice in the last four years. For the last year the jaundice has been continuous.

Operation.—November 1, 1893. Found gall-bladder very much contracted; filled with a dozen calculi. Firmly adherent throughout; evidence of old pericystitis. Duodenum adherent. As the approximation to duodenum could not be made, the gall-bladder was incised. Stones removed and the drainage-tube button inserted and packed around with iodoform gauze. The button tube liberated itself on the tenth day. Two calculi followed it, which evidently had been returned from the ducts into the bladder. Jaundice disappeared. Sinus closed on twenty-first day. Patient about the ward on twenty eighth day. Discharged from the hospital December 6th.

The number of cases of operation by incision and drainage, in literature, is twenty-three, with four deaths, a mortality of about eighteen per cent. As this is not an operation of election, the peculiarities of the individual case will be the guide to the surgeon as to when it must be performed.

3. Suture of the Gall-bladder with Secondary Incision—Cholecystostomy in Two Sittings.—The serous surface of the gall-bladder is united to the margin of incision in the abdominal wall, and a sufficient time is allowed to elapse for adhesions to take place, from five to fifteen days; then an incision is made into the gall bladder and its contents allowed to escape. The operation was first suggested by Carri, and executed by Blodgett and Kocher in 1878. Courvoisier collected 32 cases. Riedel operated in this manner 34 times, 11 of these are included in Courvoisier's report. I find in the literature from June, 1890, at which time Courvoisier's report was published, to February 28, 1893, but 4 cases, with the exception of those of Riedel (23 cases), making a total of 59 cases with 6 deaths, or a mortality of ten per cent. Of the patients that left the hospital about thirty-four per cent. were discharged with a fistula, these had an average treatment of two and a half months. Riedel has championed this operation from the beginning and has persistently adhered to it, while other surgeons have taken up the operation of one sitting, as shown by the statistics, only four operations of this kind being reported since June, 1890. Bardenheuer, Langenbuch, Mikulicz, and Lauenstein have been strong advocates of this operation in the order mentioned, but have all deserted it, notwithstanding its favorable statistics, leaving Riedel alone its great advocate. The indications for this operation are the same as for cholecystostomy of one sitting, to be mentioned hereafter.

4. Cholecystostomy in One Sitting—Suture with Immediate Incision.—The first operation of this kind was performed on July 15, 1867, by Bobb, who was making a laparotomy on the diagnosis of ovarian tumor, this being the first laparotomy-opening of the gall-bladder and cholecystostomy of one sitting. Without a knowledge of this case, in the years 1878 and 1879, Marion Sims, W. W. Keen, and Lawson Tait performed the same operation without previously diagnosticating the case. This operation was named by Lawson Tait "ideal cholecystostomy;" it would be more appropriately termed unnatural cholecystostomy, as it is not natural for the gall-bladder

to empty on the surface of the abdomen. The term "natural cholecystostomy" should be reserved for the operation known as cholecystenterostomy, because the bowel is the natural receiver of the contents of the gall-tracts. From that time there have been collected by Courvoisier 120 cases, by Riedel 12, and by myself 69, making a total of 201 cases. The histories of many of these cases are very defective, first, as to the previous conditions; second, as to the *status præsens* and clinical history; third, as to the condition when discharged. Tait operated upon 57 of these cases. In the very great majority he leaves out all the particulars above mentioned. In many he does not mention whether the fluid contents of the gall bladder was gall, hydrops, or pus, and in others he does not mention even the presence or absence of stone, though this item is less frequently omitted. I find in 163 cases, stones reported in 112, and in about seventy-five per cent. of these the stones were situated only in the gall-bladder; in about twelve per cent. in the gall-bladder and cystic duct; eight per cent. in the cysticus alone; three per cent. in the choledochus and the balance scattering. In all cases where found, the stone was extracted from the gall-bladder at the time of operation. In other cases where stones were situated in the ducts, a lithotripsy was performed, either by the fingers, by forceps, or by passing a needle through the wall of the duct and fracturing the stone. In other cases the stones were pressed onward out of the duct into the intestine or back into the gall bladder; in still others they were cut down on in the duct and removed through its wall. Of this I will speak later. The mortality in the two hundred and one cases of cholecystostomy, while the patients were still under treatment, was thirty-nine, or about nineteen per cent. The number of cases discharged with fistula cannot be approximately determined, as Tait's report is incomplete and excluded. From other statistics we have discharged with fistula about thirty-one per cent., and with the same exclusion as above, complete recoveries fifty-one per cent. We see that the mortality in the one-sitting was less than in the two-sitting operations, in one case being ten per cent., and the other nineteen per cent.; but still the outcome as to the ultimate complete recovery is approximately the same as in the operation of one sitting, and not a promising one for the patient. Still, some surgeons have had brilliant results; Dr. H. O. Marcy, of Boston, says: "It is safe to predict that the future history of operative measures for the relief of biliary obstructions will furnish one of the most brilliant chapters in surgery. One of the most serious of all the abdominal diseases, as evinced by acute pain, prolonged suffering, and great mortality, confessedly without remedy by internal medication, cholecystostomy offers help to the hopeless with an attendant danger in the hands of an experienced surgeon of as small a percentage as in ovariotomy."

Cholecystostomy by Means of the Murphy Button.—This operation can be performed with the anastomosis button in much less time and with much greater safety than with suture, in the following manner: The gall-bladder is secured and one-half of the button is inserted the same as in cholecystenterostomy; an artery forceps is then pushed through the parietal layer of the peritoneum, one-half inch to the side of the incision, grasping the stem of the button inserted in the gall-bladder and drawing the stem through the opening made by the artery forceps; pass the traction cord through the other half of button and press the button together. Sew up original opening in the peritoneum with catgut. You have now secured a firm, permanent approximation of the surface of the gall-bladder to the parietal layer of the peritoneum, as shown in Fig. 4. The gall-bladder will drain through the button, and if the button drainage tube is used the discharge can be brought to the surface without coming in contact with the wound. This operation has the advantage over the suture approximation, 1, in the great saving of time; 2, simplicity and ease with which it can be accomplished; 3, it insures perfect coaptation and no danger of leaking at the side, or giving way, as is the case with the suture, which occasionally causes death; 4, it leaves a large opening. As soon as the pressure atrophy is completed gall-stones may be extracted through this opening and a perfect drainage kept up. I am always in favor of performing cholecystenterostomy where it is possible, still if the pathological conditions require a cholecystostomy, this is by far the most simple, rapid and safe means of operating.

5. Incision of the Gall-Bladder, Removing its Contents, Suturing it to the Abdominal Wall with Immediate Extra-peritoneal Suture of the Incision Made in the Gall-Bladder.—I am unable to find but four cases of this kind reported. The operation has never found great favor with surgeons. Of the four cases operated on, three terminated successfully and one fatally, a mortality of twenty-five per cent. It was intended to take the place of cholecystendysis and to diminish the danger by having the suture in the gall-bladder extra-peritoneal, so that if the suture should give way or leak, the contents would escape on the surface instead of into the peritoneal cavity.

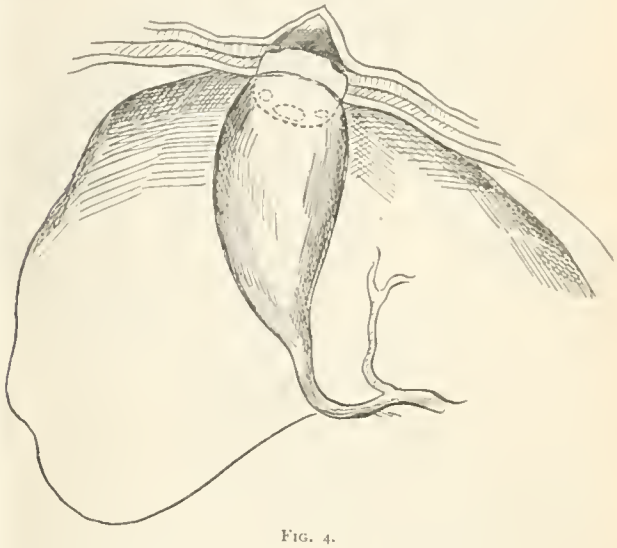

Fig. 4.

6. Cholecystendysis.—Incision of gall-bladder with immediate suture and reposition into abdominal cavity; ideal cholecystotomy. This operation on the gall bladder is a natural outgrowth of the desire of laparotomists to immediately and permanently close the abdomen at the time of the operation, as in the intra-abdominal treatment of pedicles in gynecological operations. I find 35 cases of this kind in the literature, with 8 deaths and 27 recoveries, a mortality of twenty-three per cent. The cause of death was: In 1 case collapse, in 2 cases anuria with collapse, 3 with high fever and peritonitis. All of the immediately fatal cases (6, or seventeen per cent.) terminated within seventy-two hours after the operation. The remaining 2 terminated later. What was most feared in this operation was that the stitches would give way under the tension of the gall pressure, and that the contents of the gall-bladder would escape into the peritoneal cavity. Langenbuch and Tait were very loud in their declaration that this accident would occur, and Tait, in his article in the *Edinburgh Medical Journal*, October, 1889, stated that the operation terminated fatally in every instance, while in reality up to that time there had been sixteen operations with ten recoveries, and in not one of them did the accident, "giving way of sutures," as Langenbuch and Tait had predicted, occur. This is a very noticeable illustration of an error of common occurrence. It shows how erroneous the opinion of great men in surgery may be on operations, suggested and performed, which are not in line or in harmony with the ones they are accustomed to perform; the calamity which they so forcibly predicted and deemed inevitable was the one that never occurred. While the cause of death was not

from giving way of sutures, the mortality was great, being about one third of all the cases operated on. This great mortality has rapidly told against the operation, so that it is now rarely performed and is not to be recommended.

7. Cholecystenterostomy. Gall-bladder and Intestinal Fistula—Gall-bladder and Intestinal Anastomosis.—The idea of this operation was suggested by nature in establishing pathologically a fistula between the gall-bladder and the intestine. In this way the surgeon was guided to the best means of relief where an occlusion of the duct was produced by the pressure of an impacted concrement, a neoplasm, a cicatricial band, or any pathological lesion which would render the common duct impervious. While nature had thus blazed the way, surgeons were slow to take advantage of its suggestion. The first one to advise this method was my late friend, the lamented von Nussbaum, of Munich, in 1880. He expressed himself in the following words: "When the escape of gall through the natural duct is no more possible, the question arises, can we not make an artificial connection between the gall-bladder and intestine through which the gall can again escape into the intestinal tract," etc.

The first to work out a feasible plan for the attainment of this ideal result was von Winiwater. Between July 20, 1880, and November 14, 1881, he had under his care a man with occlusion of the ductus choledochus, on which he operated six different times, and finally succeeded in establishing a fistula between the colon and the gall-bladder, after sixteen months of labor. His original plan was to perform the operation in two sittings, but all sorts of difficulties beset his way. It is wonderful what energy and persistence both the operator and patient showed to overcome all impediments. After the publication of his most difficult task it was six years and a half before a surgeon was found who had the courage to undertake a similar operation, when Kappeler undertook to follow in the footsteps of Winiwarter, but to do the operation in one sitting.

In the meantime there were several experiments made on animals, with the hope of discovering a means of making a communication between the gall-bladder and the intestine at one sitting. Dr. J. McFadden Gaston, in 1883, experimented on five dogs, with elastic suture, which was so placed as to approximate the gall bladder and intestine, and around this a row of serous sutures to protect the peritoneum. He hoped by the elastic pressure to produce an atrophy and establish a fistula. The results were unfavorable. In one the dog escaped; two ended in peritonitis; one in abscess between coils of intestine—here the ligature sloughed through into the gall-bladder and left but an extremely small opening; and in one, at the end of the eleventh day, there was found sufficient adhesion and the fistula was established, the ligature being found in the intestine. In 1884 he used a similar ligature on a young dog, in the same manner, with a good result. In 1886 he made several similar experiments, with the addition of ligating the common duct, but the dogs only lived a few days, dying of extensive gall infiltration in the liver. He deserves great credit for energy and ingenuity as a pioneer in this field.

G. Harley suggested the approximation with the formation of fistula from the gall-bladder to the intestines by means of sutures and caustic potash. He arranged a number of sutures in a small circle, about the size of a dollar, holding the gall-bladder to the bowel, but before completing the circle mentioned, cauterized the centre with caustic potash, then completed the circle with sutures, and in that way hoped to produce a fistula of the gall-bladder and have an adhesion by plastic exudation surrounding it. He claims to have had good success in animals.

Colzi, in 1883, put in a circle of sutures similar to Harley's, but before the final suture made an incision in the centre into the gall-bladder and duodenum, also ligating the choledochus. The animals tolerated the operation without any apparent disturbance in the digestive functions.

De Page, in 1887, performed the same experiment as Colzi, on three dogs, without ligating the choledochus. In one the dog ran away; another died of peritonitis; the third was killed at the end of six weeks, and showed an atrophy of the gall-bladder, but no fistula. Finally, Dastre, in his communication to the Physiological Congress at Basel, in 1889, published his experiments, wherein he succeeded in uniting the gall-bladder to the intestine for the purpose of studying what effect it would have on digestion. Of this I shall speak later.

So that we see to the date above mentioned experiments represented three different types: 1, The formation of fistula by chemical destruction; 2, By pressure atrophy—the elastic ligature; 3, Careful suturing, with subsequent incision within the circle produced by the sutures.

The priority of the operation certainly belongs to Monastyrski, for he performed his operation about a month before Kappeler, but did not publish it until eleven months after the operation. Of the seven operations performed, four were for carcinoma of the head of the pancreas, one for carcinoma of the duct at its orifice, and two were for impaction of gall-stones—those of Terrier and Courvoisier. The technique in all of the above described operations was somewhat similar, the suture being used as the means of approximation; Terrier used a rubber tube to keep the opening patulous, which was passed on the eighth day. The seat of the operation in Terrier's case was the duodenum; in Monastyrski's case, the jejunum, 2 m. below the duodenum; in Kappeler's 226 ctm. above the cæcum; in Fritzsche's case 3 m. below the pylorus.

There remained the cases of Bardenheuer, who performed two operations, where he united the gall-bladder to the small intestine with an elastic suture in the centre and a single row of silk sutures around it, expecting that the elastic suture would produce a pressure atrophy, and that a fistula would remain. The first case, impacted gall-stone, terminated fatally at the end of four weeks, and the fistula was not yet established, *nor had the gall-bladder adhered to the intestine*, a biliary fistula opening into the peritoneal cavity. The second, he writes to Terrier, was done in the same way, with the same result. To this list, taken from Courvoisier, may be added two by Czerny, one of which died of hemorrhage, and the other from exhaustion; one of Körte, one by Helfreich, and one by Redus, making, up to date, November, 1892, in all, thirteen cases of cholecystenterostomy of one sitting. Of these six died as the result of operation—Fritzsche's, two of Bardenheuer, two of Czerny, one by Körte; five died as a result of the malignant diseases from which they were suffering, and two survived, Terrier's and Courvoisier's, making a mortality of forty-six per cent. as an immediate result of the operation. Including the above I have collected in all twenty-three cases with eight deaths as the immediate result of operation; mortality, thirty-five per cent.

The various operators, in commenting on the technique of the operation, all agree that it is one of extreme difficulty, and while the experience of the others was not as trying as that of Winiwarter, it was always most difficult of performance with suture, and occupied an hour or upward to complete the operation.

While reading of the great difficulties experienced by the operators mentioned in performing this operation, I realized that the profession was sorely in need of some more simple and perfect means for the approximation of the gall-bladder to the intestine, and, after trying several devices, I succeeded in producing and perfecting the anastomosis button, which I think fulfils all of the indications. The button is inserted in the following manner:

An incision is made from the edge of the rib, two inches to the right of and parallel to, the median line, extending downward three inches. The gall-bladder is drawn into the wound, also the duodenum. The duodenum is cleared of its contents by gentle pressure with

the fingers. My short intestinal compression forceps are placed upon the duodenum to prevent the escape of gas and fluids after the incision is made. A needle with fifteen inches of silk thread is inserted in the duodenum directly opposite its mesentery, and at a point near the head of the pancreas. A stitch is taken through the entire wall of the bowel, one-third the length of the incision to be made. The needle is again inserted one third the length of the incision from its outlet, in a line with the first, and brought out again, embracing the same amount of tissue as the first. A loop three inches long is held here, and the needle is inserted in a similar manner, making two stitches, parallel to the first, in the reverse direc-

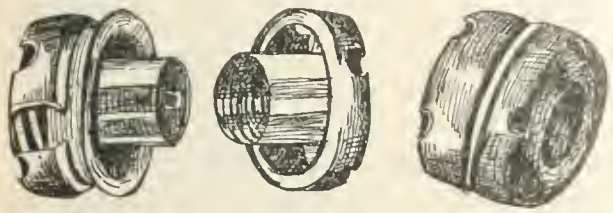

Fig. 5.—Button.

tion, and one-eighth of an inch from it, coming out at a point near the original insertion of the needle. This forms a running thread, which, when tightened, draws the incised edge of the bowel within the cup of the button. In the gall bladder a similar running thread is inserted. An incision is now made in the intestine, in length two-thirds of the diameter of the button used. The button (one part of it) is slipped in, the running string tied, and the button held with the forceps. An incision is then made in the gall-bladder the same length, and between the rows of sutures, the button (the other part of it) is inserted in a similar manner, and the running string tied. The forceps are removed and the button parts are held between the fingers and pressed together. A sufficient degree of pressure must be used to bring the serous surfaces of the gall-bladder and intestine firmly in contact and compress the tissues. The elastic pressure of the spring cup of the button produces a pressure atrophy of the tissues embraced within the cup, and leaves an opening as

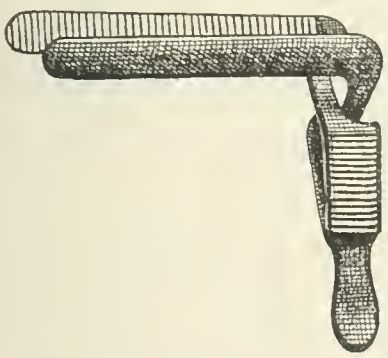

Fig. 6.

large as the button, the button dropping into the bowel and being passed through the intestines.

It takes about as long to describe the operation as to perform it. The time occupied with the first patient on whom I operated was eleven minutes from the entering of the peritoneal cavity until the closing of it. On dogs I was from eleven to eighteen minutes in performing the operation, the latter time being on the first dog, before I had made the various improvements in the technique and button. The operation is more difficult to perform on the dog than on man, as it is more difficult to bring the gall-bladder into the wound.

To show that this operation is one that the busy surgeon will be frequently called upon to perform, now that the technique is simple, we have only to reflect on the number of cases of chronic jaundice from obstruction of the common gall-duct, requiring some operation for relief, and to draw attention to the defects of the operations now in vogue, namely, the unpleasant and sometimes dangerous sequence of cholecystostomy, and external biliary fistula, which may of itself be a menace to life, and require a second operation even more critical than the first (as is shown in the reports by Courvoisier): also the difficulties and dangers of cholecystectomy and cholecystendysis.

When we consider that in cholecystostomy patients re-

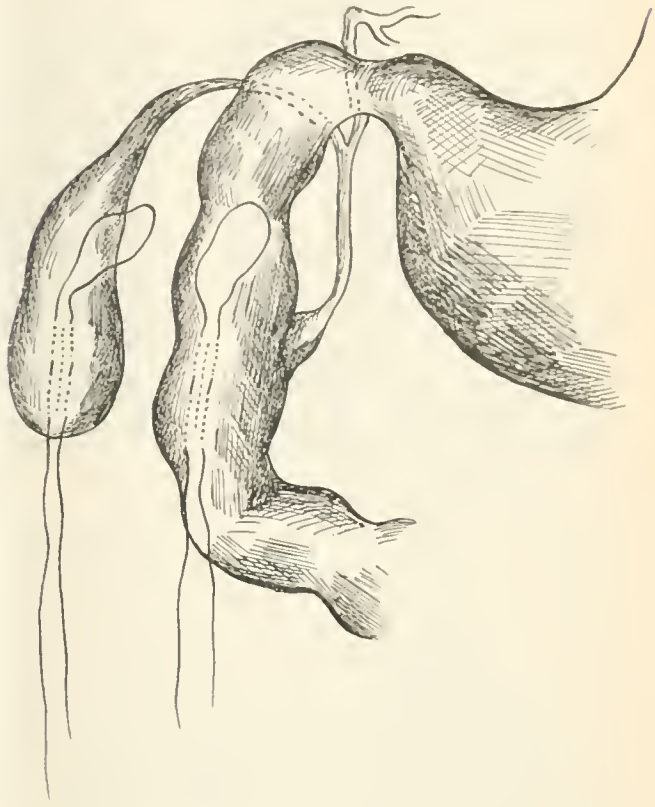

Fig. 7.—Sutures in Gall-bladder.

quire two operations, and that the quantity of bile discharged in each case requires at least two dressings a day for two and a half months, representing an enormous amount of labor for the surgeon and attendants and a very protracted and unpleasant convalescence for the patient; also when we consider that but fifty-one per cent. left the hospital with complete recovery, we can see how very much the profession is in need of some better plan

Fig. 8.—Gall-bladder Buttoned.

of treatment of the lesions of the gall-tracts than the cholecystostomy by one or two sittings. Take into consideration also the injurious effects of a permanent fistula and we have another very potent reason for abolishing the external opening.

The effect of a permanent fistula of the gall-bladder and constant escape of bile secreted, as frequently follows

cholecystostomy, is different, depending, first, on the quantity of bile that escapes from the opening, and, second, on what proportion is admitted into the intestinal tract. These facts have been lost sight of by many of the surgeons that have operated and had an external fistula remain, which accounts for the great differences of opinion as to the gravity of a biliary fistula. Where the fistula of the gall-bladder allows only a portion of the bile to escape, the patient and animal, as in Dastre's experiments, can live without suffering from the loss; that is, they are capable of digesting with a much smaller quantity of bile than they naturally secrete. But if we let the entire quantity of bile escape through a fistula the patient soon succumbs. This is thoroughly demonstrated by the twelve cases collected by Courvoisier. All patients died when the entire quantity of bile secreted escaped through the fistula, and where a large proportion escaped the patients became emaciated and sick. Therefore a safe means of allowing the gall to re-enter the intestine should be welcomed by the surgeon and patient. This operation will produce the same favorable revolution in the surgery of the gall bladder, that the intra-abdominal treatment of the pedicles did in the treatment of cysts of the uterine appendages.

Why should a gall bladder be sutured to the abdominal wall and drained any more than an ovarian cyst should be treated in this manner?

There are reported in all, up to December, 1893, 23 cases operated on in one sitting, all by means of sutures, with a mortality of thirty-five per cent., or 8 deaths in 23 cases. Since June 11, 1892, up to date, December 1, 1893, there are 17 cases of cholecystenterostomy operated on for gall-stones, by means of the anastomosis button, with 17 recoveries, one hundred per cent. One each by Dr. E. W. Lee, of Chicago; Dr. W. J. Mayo, of Rochester, Minn.; Dr. Fabrique, of Wichita, Kan.; Dr. Alex. H. Ferguson, of Winnepeg, Manit.; Dr. W. B. Rogers, of Memphis, Tenn.; Dr. Luken, of Chicago; two by Dr. F. S. Hartman, of Chicago; one by Dr. Laine, of Media, Pa.; and eight by myself. In all of these cases the result has been a complete restoration of health and no recurrence of symptoms, as will be seen by the following histories. I have had all of my cases and those of Drs. Lee and Hartman visited quite recently, and they are all in excellent health; in not one did the symptoms return as was feared by Dr. Abbé. There was one operation by this method, by myself, in which the lesion was carcinoma of the pancreas, case referred to me by Dr. Keefer, of Sterling. The duodenum was involved in the carcinoma and could not be used in approximation; a loop of the small intestine was drawn into the opening in the abdomen and approximated to the gall-bladder with the button, and the patient died at the end of the fourth day. The post-mortem showed the button in position. It was found that the bowel had been twisted upon itself in the operation and a complete obstruction produced, the same as in volvulus. This accident is an impossibility if the duodenum is used for the approximation, and I wish to call special attention to its possibility, as it is so easily avoided when it is anticipated. There was a cancer in this involving the greater portion of the pancreas, including the duodenum and the common duct. The period of convalescence was in all cases very short, and the patients were not seriously sick immediately after the operation.

This operation is indicated: 1, In all cases where it is desirable to drain the gall-bladder for accumulations therein; 2, in all cases of perforation of choledochus into abdominal cavity, where the duct must be obliterated by the reparative process; 3, in all cases of cholelithiasis where obstruction of duct is present, or where the reflex disturbances of digestion are marked; 4, in all cases of cholecystitis either with or without gall stones; 5, in all profusely discharging biliary fistulæ, either following operations or as sequelæ of pathological changes in gall-tract.

The cases in which this operation should not be performed are: 1, All cases where the gall-bladder is too small for the insertion of the button; 2, where the adhesions are so extensive that the bowel cannot be brought into contact with the gall-bladder without kinking; 3, where the ductus cysticus is obliterated, in which cases the operation of cholecystectomy should be performed where there is an absence of adhesions around the gall-bladder; 4, where we have an enormously enlarged gall-bladder with an elongation of the ductus cysticus, and without an obstruction in the ductus choledochus, in which case cholecystectomy should be performed. If the ductus choledochus be occluded, the gall bladder should be amputated just above the neck, leaving a sufficient portion in which the button can be inserted in the end and the approximation made to the duodenum in the usual way. By this operation we provide again a channel for the escape of the bile into the intestinal canal.

(To be continued.)

CRIMINAL ANTHROPOLOGY.[1]

By JAMES WEIR, Jr., M.D.,
OWENSBORO, KY.

Criminal anthropology is a science the study of which is almost universal in Europe, and which in recent years has attracted marked attention both in England and in the United States. The English literature on this subject is very meagre, and I do not know of a single American writer who has written even a newspaper article that is wholly devoted to this very important science. To Professor Cesare Lombroso, of Turin, is the world indebted for the first clear exegesis of this interesting science. In 1876 he brought out his first book on this subject, "L' Uomo Delinquente," which received immediate recognition. In this work Lombroso considers the criminal, anatomically and physiologically, an organic anomaly. Heretofore he had been regarded as a psychological anomaly. "L' Uomo Delinquente" has met great antagonism, and it has happened, as Lombroso himself prophesied, that not one stone has remained upon another, yet a better edifice than the one he erected has been built from its ruins. Let us consider the criminal anatomically and physiologically. Let us consider crime a psychical deformity that shows itself clearly in certain abnormal changes in the anatomy of the criminal. The psychical being undoubtedly moulds the physical being to a certain extent, and the mind does leave its impress on the body. This article deals with the instinctive or congenital criminal alone; the so-called occasional criminal and the insane criminal belong elsewhere. The criminal's head has abnormalities peculiar to itself. The average size of criminals' heads is about the same as normal people's heads, though the smaller and larger heads exist in greater proportion than the medium sized heads. A negro criminal's head is generally more dolichocephalic than the normal negro head, and the head of a brachycephalic criminal is generally more brachycephalic than normal. In a word, the cephalic indices are exaggerated in the criminal head. There is a marked tendency toward oxycephalism in almost every instinctive criminal. This sugar-loaf form of head will be at once noticed in the sketches of the various criminals presented in this article. These sketches were made at different times, as opportunity offered, and are drawn from life. They are not selected types, but are taken at random from several dozen sketches of convicts and criminals made by myself during the last three or four years.

Lauvergne writes of the oxycephalic head as follows: "When it is complete, that is to say, when it presents a prominent base supporting an inclined pyramid, more or less truncated, this head announces the monstrous alliance of the most eminent faculty of man, genius, with the most pronounced impulses to rape, murder, and theft."

[1] Wherever the word "criminal" is used in this paper, unless otherwise specified, I mean the congenital recidivist.

A close and shrewd observer, Benedikt, regards the bilateral elevation of the sagittal suture as indicating perversity of brain function.[1] This abnormality is rare, and I have only seen it three times. It is imperfectly shown in the photograph marked Fig. 4. There is marked enlargement of the orbital arches in almost every instinctive criminal This is well shown in Sketch 1. Most criminals have receding foreheads and shallow brain-pans. Prognathism is often a prominent feature. In point of fact, six out of ten criminals' faces show it to some extent. The squareness and heaviness of the lower jaw can be readily seen in the photograph of W. C—— (Fig. 4). Prominence of the cheek bones is another well-marked feature in most instinctive criminals. Marro found it as being thirty per cent. against twenty-two per cent. in normal persons, in the case of sexual offenders. I have noticed that it is present in all kinds of instinctive criminals. The photographs illustrating this article show that all five of the instinctive, habitual criminals have it in a well-marked degree. Fig. 3 is not a recidivist, but is an occasional criminal, and does not show it. These photographs are borrowed from the cabinet of Major Owens, chief of detectives, Louisville, Ky., and are not selected types. The facial outline of a typical criminal's skull is decidedly pithecoid in character. The skull of P. J——, a violator and murderer, is strikingly like that of the pithecoid man found in the Neanderthal cave near Düsseldorf. I have drawn the skull for comparison, and the resemblance can be seen at a glance. This skull of P. J—— points, beyond a shadow of a doubt, to an atavism or reversion to an ancestral type. The Calaveras skull and the skull of the Man of Spy[1] are pithecoid skulls, and are startlingly like the skull of this modern violator and murderer.

Fig. 1.—Photograph.

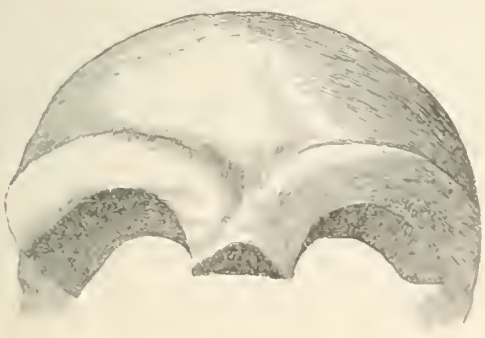

Fig. 3.—Photograph.

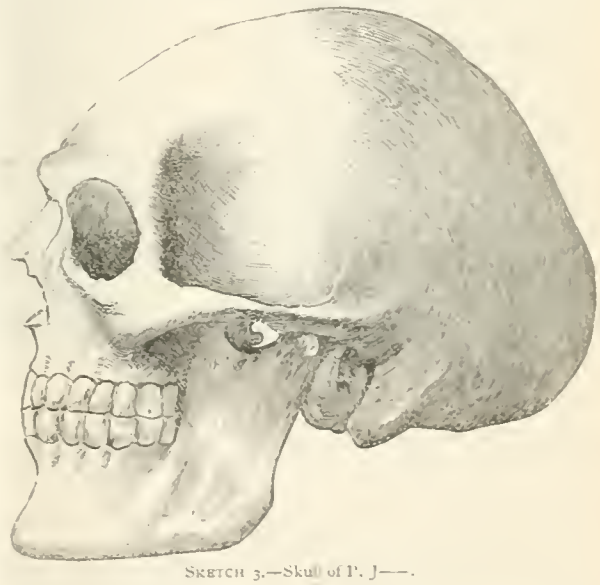
Fig. 4.—Photograph.



Sketch 1.

Sketch 2.

There are several abnormalities noticeable in the ears of criminals. Some criminals have large, outstanding ears like those of a chimpanzee or nshiego-mbouve, while others have small ears, closely applied to the skull, like those of a gorilla or orang-outang. Ottolenghi says that fully eighty per cent. of criminals have abnormal ears, and that large ears indicate a murderous tendency, while small ears indicate a thievish nature.[2] My observations lead me to coincide absolutely with Ottolenghi. I have never seen a large ear in an habitual thief, nor have I ever seen a small ear in a murderer. I have reference to white criminals alone; the criminal anthropology of the negro will be treated elsewhere. The small ear of

[1] Vide Fig. 81, p. 277, Man in the Glacial Period. Wright.

[2] Archivio di Psychiatria, 1880.

the thief is well shown in the Sketch 4, and the outstanding type of the same ear is seen in photographs Figs. 1, 4, and 5. When the thief has murderous tendencies the ear is modified and becomes elongated like the ears of Figs. 5 and 6. The criminal histories of these two last mentioned criminals testify to the truth of this statement. They are both marked in the ledger, "Dangerous: will shoot."

We have all noticed how a horse droops his ears when fatigued. Galton says that a certain school-mistress tells when her pupils are fatigued by the condition of their ears. If the ear is white and pendent the children are fatigued; if they are relaxed, but red, they are nervous.[1] This shows us how sensitive the ear is to vaso motor influences, and how intimately it is connected with the brain. Associated with an abnormal brain we may always expect to find an abnormal ear. Wardens and keepers of penitentiaries have often told me that they could tell a thief from a murderer by the size and shape of the ears.

Some anthropologists claim that certain abnormalities are found in the noses of criminals. Ottolenghi says that the criminal's nose is rectilinear and undulating, with a horizontal base; also that it is asymmetrical and always large. Professor Héger confirms many of Ottolenghi's conclusions "with reference to the nasal aperture in the cranium, by examination of the skulls of Belgian murderers."[2]

Dr. Ottolenghi may be correct in his deductions, but the measurements and observations made by myself in this direction, do not warrant an unqualified endorsement of them. I have failed to establish their truth, after making several hundred observations. Owing, probably, to cerebral congestion the criminal has very marked pallor. This, however, may be due to confinement, but I think not. A pallid criminal never sunburns, nor does he regain color after his release from confinement. His pallor, in all probability, is due to vaso-motor disturbances occasioned by habitual cerebral congestion. During the last fifteen years I have examined the brains of 23 criminals, 20 of whom were instinctive and habitual malefactors. In 19 of the brains examined I found marked abnormalities. In one, that of a negro hung for murder and attempt at rape, the cerebral fissures were very confluent, and the cerebellum was not covered by the cerebrum. In two others—murderers—there were very few convolutions, and these were lacking in depth, with little gray matter. All of these brains were deficient in weight. Some of the other brains had four anterior frontal convolutions: and one had fusion of the first and second convolutions, an abnormality peculiarly rare and striking. I have noticed in aged criminals, especially those confined for murder, a peculiar triangular fold or wrinkle at the inner canthus of the upper eyelid. This wrinkle is rarely absent in convicts over sixty years of age. This fold is also present in the aged chimpanzee, two instances of which I have noted. The precocious and aged appearance of youthful criminals is often very noticeable. This is due, in part, to the wrinkles about the eyes, nose, mouth, and temples. Here the resemblance to the anthropoid ape again crops out. I know a young lad who is an expert thief, and who is also a gambler and a drunkard, who is more wrinkled than most men sixty years of age.

In commenting on wrinkles and their invariable appearance in criminals, Ottolenghi says: "It is worthy of note, that the part of the face which, by the prevalence of wrinkles, shows most active expression in criminals, as in other degenerated persons, is that corresponding to the regions of the nose and mouth—that is to say, the less contemplative, the more material part of the face; and, in fact, we see that, with the exception of some murderers, who have surly and corrugated foreheads, the typical delinquent presents habitually in the more contemplative and rational part of his face the least degree of active expression, this corresponding to his limited psychical sensibility."[1]

A distinguished detective ("Yankee" Bligh, formerly chief of detectives, Louisville, Ky., now dead) once, in talking with me about the characteristics of criminals, spoke of a certain fixed look or stare that most malefactors have. He regarded this look as an absolutely safe diagnostic point in the making up of his criminal diagnosis. He called this stare the "ape-eye." "Look," said he, "at the next ape you see, and you will know what I mean." This peculiar stare is seen in the photographs marked Figs. 1, 4, and 6. The eyes of a thief are generally set close together; he has but little beard; the movements of his head and hands are quick and curiously ape-like. The eyes of a murderer are set farther apart; the movements of his head and body are slow and deliberate. I have often noticed this apparent sluggishness in men who have murderous tendencies. They resemble the gorilla in this respect, which is slow and deliberate until aroused.

Lombroso says that those who are guilty of rape have bright eyes; the voice is rough or cracked; the jaws large; the cheek-bones prominent; the lips and eyelids thick. The eye of the instinctive homicide is glassy and cold, the jaws strong, the beard thin. "The born criminal," says he, "has projecting ears, thick hair, a thin beard, projecting frontal eminences, large jaws, a square and projecting chin, high cheek-bones, and frequent gesticulation. It is, in short, a type resembling the Mongolian or sometimes the Negroid."[1]

Criminals show a great lack of sensibility to pain.

[2] Lombroso: L' Uomo Delinquente, p. 216.

This is shown by the extent to which tattooing is carried; criminals tattoo the most sensitive parts of the body, not even sparing the sexual organs. Physicians in charge of prisons have informed me that they have repeatedly performed minor operations without administering an anæsthetic; the criminals preferring rather to suffer the small amount of pain. The rapidity with which criminals recover from wounds has been repeatedly noticed and commented on. In this respect they are like the lower animals. A physician once told me that sick convicts reminded him of the lower animals, by the uncomplaining, patient way in which they passed through severe illnesses. Out of two hundred convicts, I found sensibility below normal in one hundred and forty six, as shown by the æsthesiometer. Wardens and keepers of prisons and penitentiaries, who have long been in office, say that criminals all look alike. One general type embraces the whole body of prisoners. A keeper in an Eastern prison (Sing Sing) once told me that "twins, triplets, quadruplets, and even quintuplets were to be found in every prison." This general type is easily recognized by most men. I showed the six photographs illustrating this article, before I had written on their faces the criminal offence, etc., of the individual photographed, to one hundred men, with the following request and explanation: "Here are six thieves; five of them are recidivists, and one of them is an occasional thief, *i.e.*, one influenced by circumstances to steal; pick out the occasional thief." Ninety-five picked out Fig. 3; three hesitated between Figs. 3 and 6; one chose Fig. 2; and one chose Fig. 5.

A criminal lawyer of Cincinnati boasts that he is able, at a glance, to tell a criminal from an innocent person.

Professor Enrico Ferri, an Italian anthropologist, once examined several hundred soldiers, and found only one whom he would judge to be a criminal from his personal appearance. This man had, in fact, been found guilty of murder.[1]

Women are excellent physiognomists, and rarely make a mistake. A young girl was introduced to a man; she refused to speak to him. On being asked by her relatives why she treated him so cavalierly, she answered, "If he is not already a murderer, he will become one." This man was Francesconti, who committed a most atrocious murder some time after. She told Professor Lombroso that she knew he was a murderer from the appearance of his eyes. Lombroso once showed portraits of twenty thieves and twenty moral men to a class of thirty-two young girls. Eighty per cent. of these girls recognized the first as "wicked people, the second as good."[2]

Everyone who has had anything to do with criminals, knows that the criminal carries on his face the imprint of his peculiar individuality. Those who watch over and restrain him in the large cities, recognize him at once without analyzing the different parts that make his whole.

"It is a matter of observation that this criminal class constitutes a degenerate or morbid variety of mankind, marked by peculiar low physical and mental characteristics. They are, it has been said, as distinctly marked off from the honest and well-bred operatives as 'black-faced sheep are from other breeds,' so that an experienced detective officer or prison official could pick them out from any promiscuous assembly at church or market. Their family likeness betrays them as fellows 'by the hand of nature marked, quoted, and signed to do a deed of shame.'"[3]

I think that I have clearly shown that the instinctive criminal is an abnormal individual. He is anti-social simply because he is morally and mentally an atavism. Or, to speak more plainly, he is morally imbecile because he has no knowledge of morality, and because he has no feeling within himself that his anti social actions are wrong. Atavism has hurled him back thousands and thousands of years, and has placed him beside his pithecoid ancestor. He is a savage in the midst of civilization. His emotions and desires, his responsibilities and religion are those of an autochthon, born and dead centuries and decades of centuries ago. We send our intellectually insane people to asylums where they are presumably treated with kindness and consideration. We incarcerate our moral imbeciles in penitentiaries, prisons, and workhouses. We feed them on poor food, and drive them to their tasks in the shops or the mines, with the fear of the whistling lash, or the maddening terrors of the dungeon ever lurking in their hearts. We bind them to the chair of death, and rend their souls from their bodies with the lightning's stroke; or we place ropes about their necks, and hurl them into eternity through the falling doors of the scaffold. Poor unfortunates! Are they to be held responsible for Nature's vagaries? Enlightened humanity has a difficult problem to solve, when it is asked the question, "What will you do with the Criminal?"

ELONGATED CERVIX UTERI—OVARITIS—OSMOTIC TREATMENT.

By WALTER S. WELLS, M.D.,
NEW YORK.

The subject of this sketch has been married about two years, and came to this city last spring for surgical treatment, having previously been under medical treatment in her Western home.

In addition to the abnormal cervix mentioned as complicated with ovaritis of the left side, there was also anteversion, and endocervicitis, with erosion, as correctly diagnosed by a St. Louis physician formerly in charge.

The natural dread of undergoing a surgical operation, with its attendant dangers from anæsthesia and possible secondary complications, restrained her from submitting to the ordeal, so that it was postponed from time to time.

In the meantime it happened that the writer was successfully treating, by the osmotic system, a case of uterine tumor in the person of a friend of the patient—subject of this sketch—to whom she explained the method, and finally effected an interview. The osmotic treatment was the more readily accepted after it was further explained that it would certainly relieve the inflammatory conditions complicating, and place the case in a more favorable condition for future recourse to the surgeon's knife, if necessary.

The history of the case antecedent to marriage, as given by the patient, was one of dysmenorrhœa from the inception of menstruation, the painful condition of the left ovary scarcely fully subsiding between the menstrual epochs. No professional examination *per vaginam* previous to marriage, but the patient had felt, by introducing her finger a short distance, a fleshy substance, seemingly about the size of the finger itself, quite firm, and yielding only a moderate movement at its base, as her finger manipulated its end. Maiden modesty and the supposition that it was natural repressed any disclosure, and it was not until long after marriage that dyspareunia, profuse leucorrhœa, and a general aggravation of the ovarian engorgements each month, prompted an examination, which discovered the remarkable cervical elongation.

Our first examination was digital, the patient standing; and the sensation conveyed was identical, as to the size, with that previously described, only rendered more definite by our being able to trace it to its base, which the limited reach of the patient's finger had not permitted. It seemed to our sense of touch to be at least two and a half inches long, and to be fully as large as stated. It was hard and firm, not easily yielding to efforts to bend it from its rigid line of projection, but was slightly capable of yielding at its junction with the body of the

uterus. The displacement, which had existed before her arrival here, still remained.

The speculum disclosed the elongated cervix of dimensions to fully confirm the digital impressions, together with its surface in the condition of erosion, doubtless maintained by the attrition of coition. The cervical canal was so contracted that the smallest sound could not penetrate without causing great pain and bleeding.

The os was filled with a protruding mass of stringy, tenacious discharge, characteristic of cervicitis. There was considerable leucorrhœal discharge also, occasioned by the engorged vaginal mucous surfaces, and this flux, together with the Nabothian exudation, and that contributed by the erosions, came away quite profusely upon using the fountain syringe. In short, there was chronic inflammation and engorgement of the mucous membrane of the vaginal, cervical, endometrial, and Fallopian tracts, up to and involving the left ovary, especially aggravated each month as the menstrual period approached.

In the treatment of this case the first indication was to overcome this condition of inflammatory engorgement. Selecting an osmotically prepared sponge, of size suitable to act also as a pessary while effecting endosmosis and exosmosis, we saturated it with a solution composed of three fluid drachms of zymocide, one drachm glycerine, and an ounce and a half of warm water. The sponge was then introduced through the speculum, directly in apposition with the os, and surrounding, by its cup-shaped depression, the cervix, and was left *in situ* for twenty-four hours.

At the end of this time the patient, as instructed, removed the sponge by its string attachment, and having noted its condition, as to the discharges, thoroughly cleansed it and returned with it for renewed medication. Her report was that the sponge, when removed, was loaded with the glairy, tenacious excretion, and others of a puriform and mucous character.

Upon the second examination the mucous surfaces brought to view, and the erosions, were found much improved in appearance, and continued to improve as the osmotic treatment progressed. At the end of half a dozen applications of the osmotic sponge, saturated as described, the erosions were healed, the leucorrhœal discharge was very much abated, and the cervix was tangibly softening. This treatment had intentionally been commenced soon after the cessation of a menstrual period, and continued, every third day, up to the monthly recurrence.

When this supervened, instead of being accompanied by the suffering which had characterized the ordeal each month, for years, the menses escaped with so little pain that the patient could scarcely realize the fact, until ocularly demonstrated. Of course, the treatment was discontinued during the menstruations. When treatment was resumed after their cessation, examination, both digital and specular, discovered other improvements. The cervix was softened and quite flexible, very materially shortened, and its canal admitted a bougie three times the size it did at first, with no accompanying blood, although the glairy excretion continued somewhat. The enlarged uterus, overweighted by congestion, was reduced in size and was recovering from its anteversion, and the chronically painful ovary was much less remindful of its presence.

As the treatment progressed during the second month we tried many experiments, with the view of promoting resorption of the superfluous tissues of the cervix. Former experience had convinced us of the superiority of zymocide for the reduction of all conditions of engorgement to which the female pelvic organs are liable, and so in excess of any combinations of remedies strictly pharmaceutical, that we resolved to continue its use, as it had accomplished a decided advance.

We should mention that the addition of glycerine had been omitted after the first few treatments. It was decided to keep up the osmotic action of zymocide, and seek an addition to it of something to increase the resorption of the cervical excess, and this was finally accomplished by adding to it an equal amount of medicinal solution of pyrozone (three per cent. H_2O_2). The increasing shrinkage of the now soft and flabby cervix, under the application of the combined dressing last mentioned, was noticeable more and more as this treatment was continued. At the same time the cervix was gradually assuming a natural condition, its canal became more patulous, the parts, originally tapered as first described and almost impermeable, assumed the usual convex shape of the end of an egg, and a large-sized sound easily entered without the consciousness of the patient.

A still further impetus was now given to the osmotic procedures by adding to the above solutions from three to five grains of iod. potassii to each spongeful of fluid applied.

The treatment was continued at irregular intervals into the third month, as the sponge continued to bring away slight deposits of the cervical discharges of glairy mucus.

Finally, there was such a complete return to normal size of the cervix, and restoration to healthy standard of all the parts involved therewith, that the patient was discharged cured.

The New York Medical Record of May 27, 1893, published the *modus* of osmotic treatment, a copy of which we will forward upon request.

THE BABCOCK TEST AS A MEANS OF DETERMINING THE COMMERCIAL AND NUTRITIVE VALUE OF MILK (BOVINE AND HUMAN).[1]

By HENRY G. PIFFARD, A.M., M.D,

PROFESSOR OF DERMATOLOGY, UNIVERSITY OF THE CITY OF NEW YORK.

As everyone knows, the ordinary methods of chemical analysis as applied to milk (gravimetric process), with a view to the determination of its richness in oil, are tedious and impracticable except at the hand of a skilled chemist. A simpler means was therefore a desideratum, and this has been supplied by Professor S. M. Babcock, Ph.D., of the University of Wisconsin.

Babcock's method consists, first, in dissociating the oil-globules or butter fat from the casein by means of sulphuric acid and heat; second, in collecting the butter-fat in one mass by means of centrifugal action; and third, in measuring the volume of the liquid fat in a suitable graduated tube. For the convenient carrying out of this process, Dr. Babcock has devised a simple and inexpensive apparatus, consisting of a pipette, a graduated cylindrical glass, and a centrifugal holding a number of test-bottles. Some sulphuric acid and a little hot water include the accessories. With these appliances an exceedingly accurate determination of the butter fat contained in a sample of milk can be made in about ten minutes.

The test-bottle is of about two ounces capacity, with a narrow, graduated neck. The graduations run from one to ten, and each of the divisions corresponds to the percentage of butter fat contained in the sample of milk tested. The main divisions are further subdivided so that percentages as small as .2 can be easily read off. The pipette has a single graduation marked 17.6 c.c., and the cylindrical graduate has also but a single mark at 17.5 c c.

The centrifugal is a large tin drum with a cover, and inside there are supports for the test-bottles. Outside there is a gearing by means of which the bottles can be whirled at great speed.

In order to test any given sample of milk, care should be taken that it is thoroughly shaken up, so that any cream that has risen by standing shall be evenly distributed through the mass. When this is done, insert the point of the pipette into the milk and suck it up until it rises

[1] Read before the New York Academy of Medicine, December 28, 1893.

above the graduation. Place the finger over the upper end, and by admitting air slowly, allow the milk to escape until it stands exactly at the 17.6 c.c. mark. Then transfer the milk to the test-bottle, blowing out the last drop.

Next fill the acid measure to the 17.5 c.c., mark with sulphuric acid (sp. gr. 1.82), and add it slowly to the milk. In doing this it is well to slightly incline the bottle, so that the acid will run down along the side, rather than to drop it directly through the milk. When the acid is all in, shake the test-bottle slowly and with a circular motion, so as to thoroughly mix the contents. This will be accompanied with the development of considerable heat, and the mixture will become black from carbonization of the milk-sugar.

The test-bottle is now placed in the centrifugal, and the other bottles, if not used for testing, should be nearly filled with water. Next place the cover on and turn the wheel at moderate speed for exactly five minutes, the bottles are then removed from the centrifugal, and hot water is added until the fluid rises nearly to the upper graduation on the neck. The test bottles are returned to the centrifugal and whirled for one minute. This completes the operation—the cover being removed, the bottles are taken out and are ready for examination.

The entire quantity of butter-fat will be found collected in the neck of the bottle, and its proportion can be easily read off. For instance if the upper line of the butter fat is at 8 6 and the lower at 3.1; it would indicate that the milk contained five and one half per cent. of fat—which figure, however, is higher than the milk from the majority of cows will test.

The Babcock method is now almost exclusively relied on to ascertain the commercial value of milk when bought or sold in large quantities for butter and cheese making.

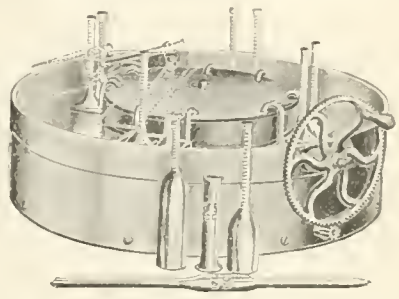
Although the Babcock test gives a direct indication only of the proportion of butter-fat contained in the milk, it is also relied on for the determination of the casein, because analysis has shown that this latter substance bears an almost constant ratio to the former; *i.e.*, the more fat, the more casein, and *vice versa*.

It will thus be seen that by means of the simple procedures here shown we can determine with great ease the proportions of the chief nutrients (hydrocarbons and albuminoids) contained in any given sample of milk. So far as I am aware, however, no definite relationship of the milk sugar to the varying proportions of the other ingredients has been worked out, and if I am correct opens a useful field for investigation.

The utility of this invention of Professor Babcock, in enabling managers of hospitals, asylums, and other public institutions to control the quality of milk furnished them, suggests itself at once.

In private families even, this test can be utilized. In my own domestic economy I had been paying ten cents a quart for the milk furnished by a well-known purveyor. A competing milkman offered to furnish "just as good" for seven cents. A few tests were enough to show that the ten-cent milk was the cheaper.

Some twenty years ago I made a good many analyses of human milk by the processes then in vogue; but, as will be understood, the time required for these examinations was more than a practitioner could well afford to give. The Babcock machine, however, now makes this a comparatively easy matter, and I find that satisfactory examinations can be made of mothers' and wet-nurses' milk without any modification of the processes here described.



The Babcock test offers also a convenient means for the examination of some of the proprietary milk-foods now so plentiful in the market.

Some months ago a sample distributor called at my office with a preparation that he declared was made only from the "best of pure country milk." After listening to the fellow's story I suspected that the thing was a fake, and on submitting his preparation to the machine found that it contained less than two-tenths of one per cent. of butter-fat. In other words, the stuff was made from skim-milk.

The Babcock centrifuge, however, can be applied to other uses besides milk-testing, as it may also be employed to obtain a prompt separation of urinary sediments. For this purpose I use bottles with a shorter and broader neck, and made, of course, without graduations. After two or three minutes' whirl the urinary sediment, crystal, casts, etc., will be found collected in the bottom of the bottle, ready for immediate microscopical examination, thus obviating the usual delay of twelve or twenty-four hours required for settling in the ordinary way. The importance of this, in enabling a physician to arrive at an early diagnosis in a doubtful case of uræmia, will not be overlooked.

Finally, those who delight to delve into the diverting depths of the fascinating science of diatomology will find this centrifuge a substantial aid in their work.

Dr. Babcock, with great generosity, has given his invention to the world, and as a consequence a dozen or more firms are engaged in its manufacture, each, however, introducing some special modification of their own. The

one here shown is known as Roe's pattern, and is made by the Creamery Package Manufacturing Company of Chicago, but can also be obtained from Richards & Co., of this city. The price of the four bottle machine, with appurtenances, is $8. Those arranged for a larger number of bottles cost a little more.

10 West Thirty-fifth Street.

The Grip.—A Latinist from Mount Holly, N. J., sends the following Horatian song concerning the "microbus aut virus, quodcumque sit," of the grip, to the New York *Sun*. The Latin is so thoroughly modern that it can be easily read in Chicago:

Cæsar Ruthenus,
Grippâ perplenus,
Torquens in lecto clamat:
"Hunc miserum morbum
Totum per orbem
Spargam, qui circum me stat!"

Tumque bacillos
Valde tantillos
Ventis distribuit sic,
Ut hi ministri
Plane sinistri,
Spargerent illic et hic.

Itaque ventis,
Minime lentis,
Ex aquilone qui fiant,
Et sordidis se Avis.
(Quippe per naves,
Quæ super Atlanticum erant.)

Pervenit nobis
Iste microbus
Aut virus—quodcumque sit—
Quo lugent populi
Rure, metropoli,
Et medicus dives quo fit

An sustinebimus?
Inulti flebimus?
Nimis molestum est, heu!
Summus casum!
Cæsaris nasum
Tundamus ego et tu.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, January 13, 1894.

THE NATIONAL QUARANTINE BILL.

THE Chicago Medical Society and the Milwaukee Medical Society have both adopted reports adverse to the National Quarantine Bill as drafted by the Committee of the New York Academy of Medicine. The reasons given are in the main that the Academy bill does not go far enough, that a full-fledged Department of Public Health ought to be created, with a medical officer at the head of it in the Cabinet. It is further argued that the Academy bill does not provide sufficiently definite qualifications for the commissioners, and that the provision which continues the quarantine under one officer of the Government while the regulations are framed by the commission (of which this officer is a member) would create confusion. Finally, it is objected that the commissioners are not to be paid enough.

Everyone has a right to his opinion, and no fault can be found because the physicians of Chicago and Milwaukee do not agree with those of other parts of the country. It is most unfortunate, however, that the criticisms which have been made so recently were not published sooner. The Academy bill was published in full last summer, copies were widely distributed and criticisms asked for. The desire was to secure the views of the whole profession and to draw up a bill which would give a practical embodiment of these views. Modifications were made in accordance with suggestions received, and the bill as a whole was the result of careful deliberation and consultation not only with experienced sanitarians but with lawyers and practical legislators.

It was felt, we believe, that the time was not ripe for the creation of a separate department. However just and wise a measure may be it is utterly impossible to force it upon a body of men who do not believe in it or upon a community which is not educated up to its necessities. The history of legislation is a succession of illustrations of this fact. There is, as everyone knows, a strong sentiment against multiplying the number of our cabinet officers, and this sentiment, however unreasonable, must be dealt with as a fact.

The present quarantine law is an advance on what we used to have. The proposed quarantine law will be an enormous step farther in advance; and it is one which we believe it will not be difficult to accomplish. Everything, however, will fail if there is a division of sentiment, and—most horrible of all—a "doctors' quarrel." We trust, therefore, that some harmony of action can be secured. The minor points regarding the executive organization of the Quarantine Bureau can easily be settled; and we trust that concessions will be mutually secured regarding all points.

It would be a lasting disgrace if any matter of sectional pride or local jealousy entered in a question of such momentous importance to the welfare of the people. We are sure that both the American Medical Association's Committee and that of the New York Academy are above any such feelings, and desire to secure a common end. If this is so, harmony can be secured and the profession can work unitedly in furtherance of their patriotic objects.

A GERMAN VIEW OF "AMERICANISM" IN MODERN MEDICINE.

A REMARKABLE article has recently appeared in the *Deutsche Medicinische Zeitung*. The author's personality is modestly concealed under the pseudonym "B. L. in W." His doleful lucubrations have been widely copied by the medical press of the Fatherland. The gist of B. L.'s terrible arraignment of modern medicine is that European, even including German therapy, is becoming rapidly "Americanized." How best to meet this depraved tendency in a downward direction is made the subject of his anxious inquiries.

The Teuton naturally stands aghast at the dismal vista opening before his dreamy eyes by the rapid strides of German medicine away from time-honored theorizing and scientific hair-splitting, into the broad domain of common-sense and the practical. That is what it means for German medicine to become Americanized.

If B. L.'s representations can be relied upon, there must be great alarm in the inner circles of German medical autocracy, where abstract science is still supposed to reign supreme, while German death-rates go on healthfully increasing.

We are told that "the American healing art has, without doubt, made extraordinary advances in the past few decades." It is indeed nothing short of disgraceful that the German public is beginning to ask German doctors to cure German ailments on the American plan.

The involuntary confessions of B. L. disclose a peculiar state of affairs. For while America still sends its annual quota of callow youths to the empire of William II., in quest of "higher medical education," the subjects of his Majesty are clamoring for transatlantic notions in the conduct of medical practice. Now, the RECORD has always believed in reciprocity. For this reason we will welcome to our shores all those German graduates who, after having been drilled in approved Teutonic methods of pure science, find themselves a trifle deficient in those minor qualifications of professional power which help to cure the patient. At the same time we are willing to send some of our own medical citizens across the waters, in order to find out the best-sounding Greek names for diseases which they have long known how to handle, though not, perhaps, to euphoniously designate. A fair exchange on such lines ought to be helpful all around.

But to return to the specific accusations of "Dr. Med. B. L. in W.": "No materia medica contains so many remedies as the American one; moreover, in variety of

form and exhibition American drugs greatly exceed European requirements." Now, that is really too bad. The revisers of our Pharmacopœia ought to be at once despatched to Germany for the radical extirpation of their bumps of vulgar extravagance. Again, "American drug stores are veritable palaces; for the Yankees are the pharmacophile people *par excellence*. The American takes daily—apart from ice-water, hot bread, and countless mixed drinks—his pills, his powders, and his fluid extracts. That is why the Americans have such poor teeth, worse stomachs, and excellent dentists. These pernicious American habits produce neurasthenia, which is really only a symptom of Western hyperculture." And this crazy hotch-potch of ice-water, biscuits, fluid extracts, bad stomachs, neurasthenia, and good dentistry is what we are seriously asked to regard as "Americanism." No wonder they are afraid of it, and are arming against its threatened invasion. We, too, intend to keep our eyes open. And as soon as the pathogenic microbe of this "Americanism" shall have been duly discovered by an enterprising Kochite, we mean to have some of it in pure culture for the protective inoculation of everybody—from the President of the United States all the way down to the latest imported anarchist and German pauper.

The great stress laid on the principle of "utility" in modern German therapy is another American innovation which B. L. denounces in sneering terms. The "ideal devotion to science has been replaced by a commercial rush after success, bread and butter, position and fame." Well, what of it? Why should the doctors starve in obscurity, while all other human beings are earnestly striving for adequate recognition of their laborious efforts?

In regard to the needless multiplication of new remedies, more particularly of antipyretics, narcotics, hypnotics, and antiseptics, we are disposed to agree with our German critic. But when he asserts that these drugs are chiefly of American origin, and especially of Western (Californian) extraction, he blunders stupidly. Germany is the native country of most of this new-fangled trash, which is thrust upon the market for purposes of sordid gain, and by no means in the interests of "purely disinterested science." The country that has given the world its tuberculin craze is ill-prepared to sneer at the land which has left to humanity the lasting heritage of chloroform anæsthesia.

When the erratic B. L. next takes up the cudgels to pound modern excesses in specialism, we are once more heartily in accord with his strictures. His jeremiade touching the decay of the family practitioner also contains a timely warning, but not one which fits our country better than Germany or the rest of the world. We quote the original as follows:

"Der moderne Hausarzt verwaltet sein dornenvolles Amt oft nur als lebender Adresskalender für Specialisten, er ist fort und fort auf der Suche nach den allerneuesten Heilmitteln und Kurmethoden. In dieser wilden Jagd spielt er die traurige Rolle des Gehetzten, denn der Patient geniesst zum ersten Frühstück bereits einen pikant zurechtgemachten Aufsatz über irgend ein neues Heilmittel gegen Diphtherie, über den Unterschied zwischen Asepsis und Antisepsis, oft kaum 2 Tage, nachdem der Urheber einen der vielen medicinischen Congresse mit seiner Neuigkeit beglückt hat — und drängt novarum rerum cupidus den Arzt auf die schiefe Ebene des Probirens. Dass das therapeutische Pfuschertum in den wie Pilze aus dem Boden schiessenden Sanatorien, Nervenanstalten, Heilinstituten, Kurorten zum Ausdruck kommt, ist nur zu bekannt."

Again, when B. L. denounces the flourishing industries of massage, the "Kneip-Kur," suggestion-therapy, and similar fads, he inveighs unwittingly against Germanisms, not Americanisms. In fact, we fear his knowledge of the United States was exclusively evolved from his inner consciousness. Actual experience of American medical affairs he has had none. It is not surprising, therefore, that he knows so many things about us which are not so. Foreigners often do.

On the whole, we are not disposed to find too much fault with our German critic. He has said in plain language that American doctors are the best practitioners now extant, especially from the stand-point of advanced therapy. American medicine will presumably continue to draw lofty scientific inspirations from Teutonic sources. At the same time, however, we will continue to teach foreign flounderers how to treat individuals afflicted with disease in a rational, effectual, satisfactory, and humane manner. The modern world has room both for German thoroughness, and American practical common-sense, in all that relates to the healing art.

THE BLIND CHILD AND THE CULPABLE MIDWIFE.

We are pleased to know that something has been done to compel midwives in charge of a case of confinement to give heed to the law which requires them to report to the Board of Health or to a registered physician the fact that a baby under two weeks old has any inflammation of the eyes. Such a law has been in existence, but has not hitherto been enforced, partly because the law was until within a year not fully operative in its terms, and partly because sufficient evidence could not be had to convict an offender.

The Society for the Prevention of Cruelty to Children secured a year ago a modification by which the law was made more effective, and has just obtained the conviction of a midwife, who pleaded guilty to the offence charged. The child was brought to the New York Eye and Ear Infirmary when four weeks old, with both corneas perforated, and it is now totally blind. The midwife ceased attending the mother on the ninth day, and directed her to apply breast-milk to the child's eyes. She said that the eyes were not seriously affected, and would soon be well. She did not see them again for some time, and then advised application to a dispensary. Her offence consisted in giving treatment to the child and in not making a report of the case as the law directs.

She was fined $5, and reprimanded by the judge; but the law makes the offence a misdemeanor, of which the full penalty is much more severe. The midwife's plea of guilty, and that she (a German) was wholly ignorant of her duty under the law, was the reason for the lenient punishment. It is to be hoped that physicians will give attention to this matter, especially such as practise in dispensaries and eye institutions, and by giving evidence to the Society above-named they can help to accomplish a much-needed reform. The cases of ophthalmia neonatorum are, in the great majority of cases,

easily controlled if treatment of the proper kind is begun early. Among the poor the cases are most frequent, and hence the need of holding the midwives, whom the poor usually call upon in accouchement, strictly accountable to the law. The time of two weeks permitted by the law ought to be shortened to one week within which the midwife should give notice.

THE GIFT OF A MEDICAL LIBRARY.

The generous gift of Professor Senn to the Newberry Public Library deserves the warmest commendation. By virtue of this, Chicago is at a single bound placed in possession of a medical library nearly as large as that in any city of the United States except Washington. The value of such a library to the profession of Chicago cannot be over-estimated, and we must congratulate our brethren of that city upon their acquisition.

Professor Senn's gift reminds us that there is near this city a collection of books equally unique, and perhaps quite as valuable, which has, we believe, not yet been put into the hands of the profession. We refer to the library of the late Dr. George P. Fisher, of Sing Sing. It is greatly to be hoped that in some way this collection may be obtained for the Academy of Medicine. Dr. Fisher's library was particularly rich in works on teratology, in ancient and rare classics, and in monographs on all subjects.

HOSPITAL APPOINTMENTS AND ADVERTISING.

The editor of the *Medical Times and Hospital Gazette* publishes some severe strictures on certain aspects of the hospital appointment question. He says that, among hospital physicians and surgeons, quackery and humbug are not altogether unknown, but what we most complain of are the bold and shameless methods of advertising adopted by consultants to obtain practice. Many persons labor under the delusion that medical men give their services to hospitals purely from charitable impulses, but we fear if those only who desire to promote works of charity gave their services to hospitals, there would be considerable difficulty in filling up the medical staffs of these institutions. The most effective and most legitimate method of advertising is through a hospital appointment, hence the desperate efforts made by aspiring consultants to become attached to these institutions. Of course, all who aspire to consulting practice cannot obtain posts on the staff of an established hospital, but the difficulty is easily surmounted. If a physician or surgeon has decided to commence practice as a consultant and finds that his services are not required by existing institutions, he has only to get two or three other equally ill-used individuals to join him in running a "show" of their own. A dilapidated house having a shop-front is secured in a poor and crowded neighborhood, and in a few days, by the liberal use of paint and varnish, the whilom rag and bone mart is converted into a much-needed (?) hospital, the claims of which are widely advertised by the professional cadgers who are always ready to collect subscriptions to help the cause of charity, on condition that they are paid a liberal commission. Our large towns swarm with these bogus medical charities, the vast majority of which are not only unnecessary but are actually mischievous, as they attract subscriptions from the public which would otherwise be given to deserving institutions. It is surprising that the men who run these "shows" are recognized by the leaders of the profession. If the "nobility of the profession" so much talked about had any existence, medical men associated with bogus hospitals and dispensaries would be shunned by all honest practitioners of medicine. But what do we find? That they are received with open arms by those who are regarded as the best men in the profession.

Although these institutions were intended primarily for British consumption, they are not wholly inapplicable in our own country. We certainly want fewer public appeals for new hospitals having no better *raison d'être* than the private ambition of a coterie of physicians.

By posing before the public as philanthropic managers or unselfish "consultants," by soliciting financial support from wealthy people, by getting up widely advertised benefit entertainments, by issuing alluring circulars and other appeals to the laity, doctors unknown to fame may for a time derive some personal benefit from their self-imposed tasks and appointments. But the New York public is apt to be discriminating. The old established institutions serving legitimate purposes, will scarcely be made to suffer much by a diversion of funds to alleged charitable establishments of the newer kind, organized solely for the "business" that it is hoped they will bring to the medical aspirants who promote them. All institutions of the pseudo-hospital variety ought to be left severely alone. The condition of suspended animation which some of them appear to be at present enjoying, may be serenely permitted to lapse into innocuous desuetude. We want no bogus charity in medicine.

Benzosol in Diabetes.—Palma (*Berl. klin. Woch.*, November 13, 1893) has used this drug, recommended by Piatkowski, in six cases of diabetes. Tables are given showing in each case the amount and specific gravity of the urine, the percentage and total daily amounts of sugar, and the weight of the patients during the treatment. In two of the cases it is shown that benzosol leaves the body in the same way as salol, the ethyl sulphuric acid in the urine being increased. The author could not find that benzosol was of any use in these cases. On the other hand, it must be given with caution, as it frequently at first produces diarrhœa, which may be dangerous in cachectic patients. In one case guaiacol carbonate was also tried, but without result.

A New Treatment for Pulmonary Tuberculosis.—G. M. Carasso publishes (*Gazz. d. Osp.*, November 2, 1893) a short note on a new method of treating phthisis. Starting from the fact that L. Braddon had obtained good results from the inhalation of peppermint-oil (*The Lancet*, March, 1888), Carasso began a series of experiments with that oil, and finally arrived at the following method of treatment: Continuous inhalations of peppermint oil are combined with the internal use of an alcoholic solution of creosote with glycerine and chloroform, to which is added peppermint-oil in the quantity of one per cent.

News of the Week.

A Correction.—In last week's issue of the MEDICAL RECORD the article by Dr. Horace Straight should be credited to Dr. Howard Straight, of Cleveland, Ohio.

The International Congress.—Italy is having a hard time in its effort to hold the International Medical Congress. Last fall there was the cholera, this winter all Sicily is in a ferment. Still the *Lancet* correspondent writes: "Up to last night the number of intending participants was 3 800—1,800 from abroad and 2,000 from Italy. The communications, scientific and practical, already received amount to 1,000 (in round numbers), although the time for sending them in does not expire till the middle of January next. More than half of these are of non-Italian origin and embody original researches and conclusions. The national committees abroad—those, that is to say, already constituted—are forty in number, while several of them, on account of the vast territorial extension of the States to which they belong, have been subdivided into various subcommittees."

A New Emergency Hospital in Boston.—A new emergency hospital, to cost about a hundred thousand dollars, is to be built by the friends and trustees of Tufts College; and the clinical advantages are to be given wholly and exclusively to the students of the Tufts Medical School.

Appointments to the State Board of Health.—Governor Flower has appointed as members of the State Board of Health Dr. John Edwards, of Gloversville, to succeed Dr. Dawes, of Saugerties, and Dr. Murray M. Adams, of Watertown, in the place of Professor Perkins.

Free Vaccination in Boston.—The appropriation of $5.000 for free vaccination has been exhausted; but the Mayor, in view of the satisfactory working of the public inoculation, has authorized the continuance of the work, and has told the Board of Health that the money expended will be granted when the work is completed. The number of persons vaccinated increased each day last week from 1,000 on the first Monday to over 4,000 on Saturday, a total of over 20,000 for the week.

A Gift to the Medical Profession of Chicago.—Professor N. Senn has given his collection of medical books, valued at about $50,000, to the Newberry Public Library. *The Journal of the American Medical Association* says that Professor Senn has for many years been engaged in the gathering of this magnificent collection, but for the most part the gems of the library were obtained by purchase from the estate of Professor William Baum, Professor of Surgery, University of Göttingen. He was one of the founders of the German Congress of Surgeons, and for fifty years had been collecting works on anatomy, physiology, surgery, and the old classical authorities. Professor Baum died in 1886, and his estate offered the library for sale. The wish of Professor Baum was that the German Congress of Surgeons should purchase the library, but that organization did not see their way clear to meet the expenses. The administrator of his estate publicly stated that Professor Baum had spent over forty thousand dollars in its purchase. The administrator offered the library to various parties, and the Royal Library of Berlin offered an almost fabulous price for a number of antiquarian volumes contained in the collection, but the administrator, following the wishes of Professor Baum, refused to separate the books, and announced that it would be sold by auction. This coming to the ears of Professor Senn, he at once secured it by making a partial payment, and then withdrew it from sale. The books were shipped to Professor Senn, then in Milwaukee, in fifty-two cases, constituting an entire car load.

Endowment for Laboratory Research in the Therapeutics of Phthisis.—The last annual report of the Adirondack Sanitarium, by Dr. Trudeau, contains this announcement: "The medical report shows the usual good results obtainable from a change of climate and an open-air life in combating consumption, and one of its most interesting features relates to those patients who have received injections of modified tuberculin. Although this form of treatment has been almost universally condemned as useless and dangerous, the results obtained during the past two years at the Sanitarium, by the careful use of a modified tuberculin, when applied in conjunction with the usual climatic and open-air methods, have been on the whole encouraging and indicate that such specific medication may, with care, be safely administered, and is probably to have a place in the future treatment of incipient consumption. It is, therefore, most opportune that through the liberality of two gentlemen, whose names at their express wish are withheld, a five year laboratory and research fund has been instituted for the purpose of defraying the laboratory expenses incurred in the study of the specific treatment of tuberculosis, and to meet the expenditure incident to any original researches on this disease which may be undertaken in connection with the Sanitarium. As far as I can learn, this is the first fund established in this country to encourage scientific observations and experiments on tuberculosis, with the hope that a broader knowledge of the disease may lead in the future to some relief from the wide spread suffering which it causes.

A Bust of Professor N. S. Davis.—An excellent bust of Professor N. S. Davis, by Mr. Starr, has been placed in the Art Institute of Chicago, where it is much admired.

Is Opium-eating a Blessing?—England, and particularly India, doesn't like to give up its opium trade, which amounts to over sixty million dollars a year. Consequently English journals, including even such a bulwark of steady habits as *The Lancet*, publish many things to show that after all opium smoking and eating doesn't do much harm. For example (we quote *The Lancet*): "According to the records of the Oriental Life Assurance Company for the last twenty years there was not a single death attributable to the use or abuse of opium of nine hundred and seventy three death-claims since 1874, and the company has upon its books something like twenty thousand native assurers. It is notorious that opium is used by some of the bravest and most energetic races of India. The Sikhs and Rajputs, for example, are fine, stalwart races, and a very considerable proportion of them take opium. We were much struck with the reported testimony of Mr. Monro, late Chief Commissioner of the Metropolitan Police, who is engaged in missionary work and is perfectly unbiased. He condemned the anti-opium agitation as groundless, and added that the

use of opium was no obstacle to missionary work." Opium, in fine, is a blessing to the English pocket, and the opium habit is a good enough habit for a Hindu.

A Four Years' Course in Seventy-one Medical Colleges.—It is proposed that the Association of American Medical Colleges adopt a rule enforcing a four years' course upon all medical students who intend to graduate in 1899 or subsequent years. The Association now embraces seventy-one colleges, and if this rule is adopted it will at once work a great change in the value of medical instruction given in America. We trust that the Association will see its way clear to adopt the new regulation.

Death of Dr. Nelson Nivison, of Burdette, N. Y.—The recent death of Dr. Nivison removes from his associates and friends a man of high standing in his profession and a frequent and valued contributor to medical literature. In the year 1861 he was elected to the Chair of Physiology and Pathology in the Geneva Medical College. In his third course of instruction microscopic anatomy was added to his duties. When the medical department of the Syracuse University was organized in 1871 he was offered and accepted the chair of physiology and pathology in that institution. Subsequently the chair was changed to physiology and hygiene. After fourteen years of service there, failing health induced him to offer his resignation, which a year or two later was accepted. He was then elected emeritus professor, which place he occupied at his death. He was born in Tompkins County, N. Y., in 1816.

Extension of Medical Course of Studies in the University of Minnesota.—The Board of Regents of the University of Minnesota have extended the course of study in the Medical College from three to four years of eight and one-half months each course. The new rule becomes operative in 1895. Perry H. Millard, Dean.

The Annual Banquet of the Medico-Legal Society of New York was held at Hotel New Netherland on Wednesday evening, January 10th. The occasion was the installation of the new president, Dr. Hubbard W. Mitchell. Judge A. H. Dailey, of Brooklyn, the retiring president, gave his farewell address and introduced the president elect, who delivered his inaugural, in which he pictured the future possibilities of the Society and the useful lines of work into which it could direct its powerful energies.

Mr. Clark Bell acted as toast-master, and speeches were made by Drs. George F. Shrady, Ralph H. Parsons, George B. Chaffee, Mr. Jacob F. Miller, Hon. Moritz Ellinger, and Dr. Isaac N. Quimby, of Jersey City. The dinner was largely attended by the members, their wives, and lady friends.

Higher Medical Education.—In pursuance of the policy recently announced in the resolution to be presented to the American Medical College Association, the trustees and faculty of the Rush Medical College have decided to require four years attendance at college from students who begin the study of medicine this year with a view to graduation in 1898; however, those who have already studied medicine one year or more with a preceptor, so that the four years of study, already required, will be completed before July, 1897, may graduate after three courses of lectures as heretofore. To encourage proper preliminary study, graduates in Arts and Sciences from high-grade colleges, and graduates in Pharmacy and Dentistry from colleges requiring a proper amount of study and two full courses of lectures, will, until further notice, be allowed to graduate after an attendance on only three courses of lectures.

The Medical Society of the State of New York will hold its eighty-eighth annual meeting in the City Hall, at Albany, on Tuesday, Wednesday, and Thursday, February 6, 7 and 8, 1894.

To Drop the Title of Doctor.—We can hardly understand in this country the extreme eagerness of English practitioners of medicine to possess the title of doctor. There has been a great deal of active discussion in English journals lately over who is entitled to the honor. Speaking of this the *American News* says: "To us on this side of the sea, who hear the title of 'doctor' given to anybody in any way associated with medicine or medicines, from the most eminent and venerable physician to the drug clerk who mixed his first prescription yesterday, the 'game would not seem worth the candle.'" One of the above writers quotes, as one of the definitions of the term "doctor," "a fish, with sharp edged spine near the tail." Webster, after giving the classic use of the term, calls a doctor: "One duly licensed to practice medicine; a physician; one whose occupation is to treat diseases." He also calls a doctor a "mechanical contrivance to serve some purpose in an exigency," for instance, "an auxiliary steam-engine, called also a donkey engine." And we are all familiar with the colloquial use of the word in the verb transitive as applied to the adulteration of liquors and foods, and the surreptitious tinkering of election returns. These considerations and many more would seem to make it advisable for the physician and surgeon to drop the term so far as practicable, contenting himself with the title of plain Mr. like other folks. Of course the public will continue to call him doctor (sometimes "Doc."), but there is no good reason why he should continue to apply to himself a term so degraded and deflected from its original high uses as to have for him no longer any distinctive merit.

The Martha Battey Hospital is an institution incorporated under the laws of Georgia and managed by a board of trustees. The buildings and grounds are the gift of Dr. Battey, in grateful recognition of the valuable aid his wife has rendered him in his surgical work at Rome. It is not designed to pauperize the people on the one hand, nor to beg contributions from the charitable, but to offer comfortable shelter and necessary food and nursing at the lowest cost to patients and their friends, thus preserving their self-respect. Dr. Henry H. Battey is the surgeon in charge, and Dr. Robert Battey consulting surgeon.

Post-mortem Idrosis.—A writer in the *International Medical Magazine* records the following curious phenomenon in a case of death from angina pectoris. "The face of the corpse seemed to be bathed in perspiration, the moisture reproducing itself after being wiped off, in spite of the presence of rigor mortis and other unmistakable evidences of death. This most extraordinary phenomenon was witnessed by several local physicians who also viewed the body. The funeral was on that account delayed several hours until decomposition had fully set in."

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 21, 1893.

D. B. St. John Roosa, M.D., President, in the Chair.

Committee on Bureau of Nurses.—In accord with a resolution passed at the last meeting, the President appointed the following committee on Bureau of Nurses: Drs. Landon Carter Gray, W. E. Bullard, Horace T. Hanks, R. Van Santvoord, S. S. Burt.

Nomination for Treasurer of Board of Trustees.—Dr. William F. Cushman, the present incumbent, was the only candidate nominated for this office.

Section Assignments.—The President reminded the members that assignments to sections were made by the Academy, and that those who wished to be identified with some particular section should make their wish known to the officers of the Academy. When members were assigned to a particular section it was expected that they would take special interest in that section. It was hoped that those who were informed of this provision of the Academy would make it known to others, that they might be assigned to their proper section.

The President also announced that the subject for discussion at the next meeting was appendicitis, and that Dr. Albert Vander Veer, of Albany, would read the paper.

The following were appointed tellers, to act at the election of officers in January: Drs. S. T. Armstrong, C. G. Currier, and W. E. Bullard.

The Babcock Test as a Means of Determining the Commercial and Nutritive Value of Milk, Bovine and Human.—Dr. H. G. Piffard exhibited the apparatus (see p. 46).

Asthenopia not Dependent upon Errors of Refraction nor Insufficiency of the Ocular Muscles.—Dr. Thomas R. Pooley read the paper. The view, which seemed to be that of some oculists, that all cases of painful vision were due to some error of refraction or muscular insufficiency, struck the author as an absurd one. Every person had painful vision at times, and it was the object of the paper to discuss those cases which were not dependent upon errors of refraction or muscular insufficiency. Among the causes, local troubles were first discussed; afterward those which acted through disturbance of the general nervous system.

The act of vision constituted only a part of a series of phenomena linked with the nervous system, and the integrity of, one might say, the entire nervous system was necessary in order that all its functions might act harmoniously and painlessly. Vision would not withhold an expression of resentment if not properly used. The first violation related to over-use of the eyes. Probably all had some time experienced the asthenopia of near vision. At first, while vision was distinct, all went along well, but after a while the objective point grew indistinct and blurred, a fact due to overstrain of accommodation with failure to properly focalize the object. At first a short period of rest might suffice to renew distinct vision, but with repeated violations vision became more painful, and one might finally be compelled to abandon his usual occupation. Such cases of painful vision were due to exhaustion of the ciliary muscle, and were called accommodative asthenopia, in contradistinction to muscular and other forms of asthenopia. The symptoms could not be overcome by glasses. An illustrative case was that of a young man who was a student of technology in Stevens Institute, who studied night as well as day, until he was obliged to quit on account of indistinct and blurred vision and frontal headache. One eye had been lost from accident. Examination showed in the remaining eye normal vision, no muscular insufficiency, no inherent defect in the eye. It was true this was an extreme case, and was aggravated perhaps by the fact of having but one eye for use; yet asthenopia in some degree from overuse of the eyes was not uncommon.

The source of illumination also had to do with asthenopia, and while the arc electric light was the more common cause, yet cases had been reported in which the incandescent light was at fault.

Another source of asthenopia was the toxic effects of certain drugs, among which the author mentioned hyoscyamin given by neurologists, also alcohol and tobacco.

Another cause was diseases of the nose, first mentioned in a paper by Dr. Noyes, in 1867, and later in a paper by Dr. Gruening, from which the author quoted freely. The close relation between the nerves of the eyes and of the nose was clearly shown by the results of slight irritation of either, resulting in lachrymation, photophobia, or sneezing, etc. Cases had been reported by different observers in which asthenopia had persisted until some nasal trouble had been cured. A practical guide to the possible efficacy of nasal treatment was to be had in the use of cocaine. Dr. Pooley's experience had corroborated what Dr. Gruening had written on this subject. Dr. Myles had also found asthenopia and other eye symptoms result from nasal disease, such as hypertrophy of the turbinated bodies and conditions causing pressure and irritation of the nerves. One of the most remarkable cases in this line was that published in the Medical Record, in 1892, by Dr. A. S. Kibbe.

Asthenopia from irritation in other parts of the body more distant from the eyes than was the nose, then engaged the author's attention. Among these were irritation of the fifth pair of cranial nerves by carious teeth, and the influence of irritation in the genital organs. One of the most common of all causes of asthenopia, in the author's experience, was uterine disease, as was shown in a paper which he had published in 1886. A later one by Morse, of Ohio, was in line with his own experience; and the late Dr. James B. Hunter had found lacerations of the cervix and other uterine affections the only apparent cause of headache, asthenopia, and especially of pain in the top of the head. His reason for believing these symptoms sympathetic was that he had found them disappear after relieving the uterine disease. Dr. Pooley added other quotations which tended to show that asthenopia might be one of the protean symptoms accompanying disordered menstruation.

As suggestive of a longer list of possible causes for asthenopia, the author named hysteria, masturbation, sexual indulgence, scarlet fever, and other exhausting diseases or habits. A very valuable paper upon those cases which fell under the head neurasthenic asthenopia, had been written by Hilbrandt, a German author, who had given credit to an American, the late Dr. George M. Beard. The treatment had to be directly largely to the general condition, and included the so-called rest cure and hygiene.

Dr. Pooley summarized the points in his paper as follows: 1. Asthenopia may exist quite independently of errors of refraction or affections of the eye muscles. 2. Asthenopia may be due to toxic causes. 3. To excessive use of the eyes. 4. To various reflex causes. 5. A large number of cases are due to irritability and exhaustion of the nervous system embraced under the term neurasthenia. 6. Rational treatment consists in arriving at the cause of which the asthenopia may be considered the symptom, and correction of the same, together with rest and systematic exercise of the eyes and use of feebly focusing glasses where there is paresis of accommodation. It is the tendency of modern ophthalmology to seek a local cause for all disturbances of vision, and to use local treatment exclusively, but this has not met with the unqualified approbation of those who seek to be physicians as well at ophthalmologists.

In conclusion, he impressed the need of a wide and thorough knowledge of all the laws which governed physiology, pathology, and therapeutics, and a wise interpretation of their relation to the special diseases which oculists were called upon to treat.

The Paper Endorsed.—The discussion was participated in by Drs. Gruening, C. S. Bull, Sayre, Page, Goffe, Myles, and the President, all of whom endorsed the views expressed in the paper.

Dr. Gruening said the paper was exceedingly timely. The oculist bore the same relation to the great body of medical men that the eye bore to the human frame. A doctor who limited his view to the immediate diseases of the eye was unworthy of his profession. It was such narrowness that had led many to lose sight of accommodative asthenopia which had been dwelt upon in the paper. Often persons recovering from some acute illness, as one of the fevers, would spend hours in bed reading a novel, straining the ciliary muscle in their exhausted state beyond the power of endurance. Next to the heart, this muscle was more constantly in action than any muscle in the body. Women who suffered most from asthenopia during the menstrual period, were likely to belong to that indolent class who would spend day and night in the recumbent posture, reading light literature, thus exhausting the power of the ciliary muscle and bringing on headache and painful vision.

Dr. Bull also thought the paper a very timely one. The woods were full of young oculists who were nothing else, who knew nothing else. Asthenopia without apparent ocular defects was, according to his observation, frequently the first sign of commencing glaucoma. He mentioned it because he had not seen it referred to in print as a possible early symptom of glaucoma. Another point dwelt upon by him was the injurious effect of long continued use of the eyes under the electric light, and he included not only the arc light but also the incandescent. Not a week passed but what he saw one or two most aggravated cases of asthenopia without other apparent cause. He could also recall six or eight cases of diabetes in which the class of symptoms described in the paper under the head asthenopia had preceded the appearance of sugar in the urine. He, too, had seen many cases of asthenopia, especially in women, connected with the condition called neurasthenia. In these patients it was common to find a faulty state of the circulation, both general and also local, in the eye, as shown under the ophthalmoscope. The calibre of the vessels, particularly of the veins, would be seen to increase and diminish during the examination. It was when the veins were fullest that the patients appeared to suffer most from asthenopia.

The conclusion to which he had come was that there were cases of painful vision in which the most careful and scientific investigation would fail to reveal any defect in the eye, in which, contrary to his former belief, there was positively no error of refraction, and in which treatment had to be directed to the patient's general condition.

Reflex Asthenopia.—Dr. Reginald H. Savre had seen several cases in his own and his father's practice, in which asthenopia had disappeared after removal of some distant source of irritation, especially removal of phimosis by circumcision. He was aware, however, that neurologists were disposed to depreciate these cases.

A Case of Diabetic Asthenopia.—Dr. R. C. M. Page spoke for general medicine, referring during the course of his remarks to a case of aggravated asthenopia, treated unsuccessfully for a long time by a distinguished ophthalmologist in a neighboring city, who, however, had directed his attention solely to the eyes. The patient then came to New York and asked Dr. Page to refer him to an oculist in this city. Before doing so he examined his urine and found it loaded with sugar. Thus it proved to be a case of asthenopia due to muscular paresis caused by diabetes. It disappeared under appropriate treatment.

The Uterus and Asthenopia.—Dr. J. R. Goffe was requested to speak for the gynecologists. He mentioned a case of painful vision in a woman whose oculist was very much frightened when he examined her eyes, fearing some grave cerebral trouble. A neurologist was consulted who agreed with the bad prognosis, although at that time the patient had shown no mental disturbance. By accident she fell into Dr. Goffe's hands, who found the uterus bound down by adhesions, and appropriate treatment directed to this condition also cleared up the objective and subjective eye-symptoms. The neurologist and oculist said they had never before heard of treatment directed to the uterus causing disappearance of a brain tumor. In another case eye symptoms disappeared presumably with the cessation of masturbation.

The Nose and Asthenopia.—Dr. Myles said he often met with asthenopia in patients who consulted him for nasal trouble, and on referring them to an oculist they were often sent back with the statement that nothing abnormal had been discovered in the eyes. While pressure on the nerves by tumors and hypertrophic tissue in the nasal passages might produce ocular symptoms, still many cases of nasal hypertrophy were operated upon unnecessarily, because belonging to the class in which this condition did not cause symptoms.

Ignorance and Humiliating Practice.—The President was quite in unison with the spirit of the paper, as was well known by those who were at all acquainted with his writings on the subject of asthenopia. Ignorance of the causes of this condition had often led to practice most humiliating to this special branch of medicine. One of the earliest symptoms in some cases of locomotor ataxia was inability to use the eyes, yet someone could be found to undertake to remedy such ocular defect by an operation. If men would only acquaint themselves with what Donders meant by asthenopia, they would not disgrace ophthalmology by trying to make of every eye what they conceived to be an ideal optical instrument. The ideal condition only existed on the blackboard or in the text books. He would not repeat on this occasion what he had before published, and meant further to elaborate, regarding muscular anomalies, neurotic asthenopia, etc.

Dr. Pooley, in closing the discussion, said he had been wondering what condition of the eye had been revealed by the opthalmoscope, which should have led a neurologist and opthalmologist to positively diagnose brain tumor when vision was normal though painful. He suspected it was nothing but hyperæmia of the optic nerve and retina, which was to be seen in extreme cases of asthenopia, without any cerebral lesion whatever. Yet it seemed to be a common mistake for neurologists to look upon hyperæmia of the optic nerve and retina as necessarily indicating a cerebral process.

Stated Meeting, January 4, 1894.

D. B. St. John Roosa, M.D., President, in the Chair.

Annual Reports.—The reports of the treasurer, librarian, and other officers were presented.

Observation upon Abdominal Surgery in Relation to the General Practitioner.—Dr. Albert Vander Veer, of Albany, read the paper. Among other indications of the rapid advance in abdominal surgery, managers of hospitals no longer passed resolutions forbidding resort to abdominal section. On the contrary, no means were now spared to make this department of surgery a success. The question arose whether the wide spread reports in medical journals, lay press, and other journals, of wonderful cures in appendicitis and other conditions, had not led to undue interference. In general, no. Had the general practitioner kept pace with the surgeon in the diagnosis of abdominal troubles requiring operative interference, and in upholding him in his work?

The author directed his remarks more particularly to the surgery of the gall-bladder and of the vermiform appendix. Hypothetical questions were put, which fitted cases in actual practice, which he related afterward, as to whether under certain circumstances the general practitioner was as well prepared to pass upon the necessity

for operative interference as he should be at the present day?

The first example related to the surgery of the gall-bladder. There was no jaundice, no gall stones in the stools, no distention of the gall bladder, surely, thought the family physician, the case must be only one of sympathetic gastric colic. Then the attacks of pain became more severe, and on careful inquiry of the patient and her husband it was learned they had at times noticed some swelling over the point of greatest tenderness; there is at times relief on assuming certain positions. The surgeon expressed the opinion that there were gall stones in the bladder and consent was given to an operation, although the family physician was in doubt. A large stone, which Dr. Vander Veer showed, was removed which ended the patient's sufferings.

In a second case the attacks of pain were attended by jaundice, passage of clay-colored stools, and at the operation no stones were found, but the gall-bladder was contracted and adherent. Loosening the adhesions gave much relief. Was it not fair to assume that had this patient been operated upon soon after it had been shown that medicinal treatment would not succeed, gall stones would probably have been found before atrophy had taken place and she would have been saved three or four years' suffering? Did the case not indicate that the general practitioner and surgeon should unite earlier for the relief of the patient? He did not mean that if the surgeon were called an operation should necessarily be performed. By an honest consulting together some conclusion might be reached which would be for the patient's good and yet spare operative interference. This happened in the next case related, and in which olive-oil and salts, which had not yet been tried, resulted in the discharge of stones, with relief from biliary colic which promised to be permanent. The next specimen was obtained at autopsy in the case of a man who had suffered from biliary colic, but had died from another disease. It demonstrated that a much larger stone could be passed through the duct into the duodenum with ease than one might have believed.

Did general practitioners fully realize the dangers connected with attacks of biliary colic? The author had known attacks to be so severe as to cause collapse and death.

One of the possible accidents in operating for gall-stone was a fistulous opening, which might prove a great disappointment to the patient unless he were informed beforehand.

The other condition in which the general practitioner and surgeon found it pre-eminently necessary to join hands was appendicitis. He had heard an able practitioner say he had treated ten cases of appendicitis with nine recoveries and only one death, which he seemed to think spoke well for medicine as compared with surgery. Yet further inquiry showed that one patient had had a discharge of pus in this direction, another in that, and so on. Would these patients have been worse off for an operation?

Dr. Vander Veer then related a number of cases seen the past few months, illustrating different phases of appendicitis and indications for operation. They included some of recovery without an operation, which he had advised, but the question arose whether they were not yet of the class which called for the intermediate operation. This was growing in favor, and the author had himself operated between attacks in a few instances of relapsing appendicitis. He also related a case of acute perforating appendicitis, and although it was recognized early by the physician, who recommended an operation and sent for the surgeon, the latter arrived some hours later, too late to save the patient. Several urgent questions suggested themselves in connection with such cases, one being whether we should not operate immediately as for a bullet wound, and whether thereby life might not be saved where hitherto the results have been so fatal.

In cases of appendicitis, in general there was the greatest need of honest and early consultation between practitioner and surgeon.

There was another somewhat unexplored field to the general practitioner where he should come in closer relations to the surgeon. He referred to tubercular peritonitis, a condition which, in a large proportion of cases, could not be reached in any other way than by section and drainage. The results of surgical interference gave encouragement for further trial.

Questions relating to pus-tubes and pelvic surgery belonged to gynecologists, and he was glad to note the closer relations which had developed between them and general practitioners the past few years.

Dr. R. F. Weir opened the discussion. He had understood the chief point in the paper to be the early coming together of physician and surgeon in order to obviate too late operative interference. He thought this point had come to be well understood by physicians in and around New York so far as appendicitis was concerned. What they wanted to know of the surgeon was, how he reached the conclusion that an operation was or was not indicated at a particular time in a particular case. Sometimes one was willing to wait twenty four hours; sometimes even forty-eight hours. Why? the surgeon's opinion was based upon signs which he had come to recognize through experience but which he found difficult to describe in words. One man might say that he placed a great deal of reliance upon the character of the respiration, another upon the character of the pulse, and so of other special symptoms. Dr. Weir would take into account the several leading symptoms, including abdominal hardness and pain, and if he found improvement throughout the circle he would not yet operate, but if one or several symptoms improved while one or more failed to do so he would operate at once. It was during the early stage that we wished to decide the question whether an operation would be necessary, for if it were done then, before very extensive inflammatory action had developed, it would be safer.

Threadbare.—Dr. Joseph D. Bryant believed that when the subject of appendicitis was raised, physicians were inclined to take to the woods, feeling that it had been worn threadbare. He had given considerable thought to appendicitis, but must admit that he never felt so much doubt and fear of his judgment when called in consultation as when about to meet a case of appendicitis. It would be readily understood, then, that so far as he was concerned the question was not yet a settled one. Notwithstanding that he had followed conscientiously the work and writings of others in this line, and had tried to formulate rules for his own guidance, yet he must admit having met with most serious and heart rending disappointments. Patients whom he had thought would recover had suddenly developed peritonitis and died; in patients whom he had believed required an operation he had found, when the belly was opened, evidences of resolution which probably would have ended in recovery without interference. He could not say always just what patients required an operation and in what ones it would be safe to postpone it. Nor did he know of anybody who could. Cases had occurred in this city and elsewhere in which eminent surgeons, after weighing all the points, had operated and found that appendicitis did not exist at all. When physicians knew of such incidents we could not wonder at their hesitation about recommending operative interference when a case arose in their family practice.

Regarding the traditional grape-seed in the appendix, he had once had the appendix examined in one hundred and fifty autopsies and in none was it found to contain grape seed or any other foreign body except inspissated fæces or muco pus.

Before closing his remarks Dr. Bryant impressed the need of closer relationship between surgeon and physician in various other fields also, especially in malignant disease.

Dr. Seneca D. Powell spoke of that which he re-

garded as the vital point in abdominal surgery, namely, diagnosis. An illustrative case was one diagnosticated by the attending physician and himself as one of appendicitis. A tumor was felt, but on operating he found a displaced gall-bladder with two large stones. He did not think the cases of appendicitis resembling, because of their severity and suddenness, gunshot wounds of the abdomen, came under the discussion, as this related more especially to indications for operation in doubtful, usually subacute, cases. The diagnosis in the former was beyond doubt, and the question of operating depended only upon whether the patient could survive it. In any case, if the indications for an operation were clear, one should not trouble himself about an exact diagnosis until the abdomen was open.

Are Doctors Afraid of Surgeons?—Dr. Charles McBurney thought it might be inferred from some published articles that the doctor had reason to be afraid of the surgeon; that it was a very ticklish matter to introduce him into the house—he would surely want to operate. He wished to assure the general practitioner that personally he did not belong to that class. The general practitioner was his friend. He brought him his cases, and he always enjoyed discussing them with him. He hoped the other party could say the same. He could appreciate the position of the physician who had attended a family for years, and was suddenly called upon to meet a case of appendicitis which required him to say whether a surgeon should be called and an operation should or should not be performed. Yet such emergencies arose and must be met. It would not do to temporize, since a little delay might prove fatal to the patient. The feeling between the physician and surgeon should be, therefore, one of confidence, and the latter should be called in time to consult with regard to the propriety of operative interference and not only after an operation had become imperative.

He had often been asked how he determined the exact time to operate in a case of appendicitis, but had not been able to express his impressions in words. But this inability to give another as clear an idea of a patient's condition as one had himself, was as true of other diseases as of appendicitis; the difference being that in them delay in treatment was permissible, whereas in appendicitis procrastination might mean death. It was experience which enabled one to reach a reliable conclusion, not alone in appendicitis, but also in pneumonia, typhoid fever, or any other disease. A description in words could not enable the tyro to reach a judgment as reliable as that of one who had observed many cases.

Dr. Vander Veer made some closing remarks, after which a recess was taken to give the tellers time to count the votes cast for candidates for office.

Officers Elected.—*Vice-President*, Joseph D. Bryant; *Trustee*, A. Jacobi; *Treasurer of Trustees*, William F. Cushman; *Member of Committee on Library*, W. Gilman Thompson; *Member of Committee on Admissions*, John S. Warren.

Treasurer's Report.—The following was the report of the Treasurer for the year ending December 15, 1893.

To the President and Fellows of The New York Academy of Medicine:

Another year of prosperity has been accorded to the Academy. An increased Fellowship and larger attendance at meetings and in the Library, bespeak awakened interest in its work. Receipts and expenditures have been greater than ever before, and the percentage of arrearage is less. The present number of Resident Fellows is 750; number added during the year, 43; number lost by death, 19; removal and suspension, 8. There are 48 Non-Resident Fellows, 40 Corresponding Fellows, 6 Honorary Fellows, and 9 Benefactors.

Receipts.

Cash, balance December 22, 1892	$1,124.09
Arrearage collected	1,705.00
Transferred from Trustees	1,500.00
Dues from Resident Fellows	12,154.00
Dues from Non-Resident Fellows	117.00
Interest allowed	64.67
	$16,664.76

Expenditures.

Salaries of Librarians and Employees		$6,008.44
Editor's expenses	$104.10	
Printing volume of Transactions	622.38	726.48
Other printing and stationery		533.79
Postage		519.49
Engrossing diplomas		18.25
Dues to State Medical Society		25.00
Quarantine Committee's expenses		79.99
Notices of deaths		59.35
Paid to collector		100.00
Coal and wood		1,428.41
Gas		153.38
Electric lighting		910.28
Ice		67.56
Repairs		101.91
Engineer's supplies		222.94
Sundries, not otherwise noted		347.48
		$11,302.75

For Library.

Binding current journals		$584.55
Rebinding books, etc.		880.45
Subscriptions to journals		1,164.73
Completing files of journals		692.38
Library supplies		306.55
New books		90.60
		$3,719.26
Balance on hand		1,642.75
Total		$16,664.76
86 Fellows are owing dues amounting to		1,865.00

Respectfully submitted,
O. B. Douglas,
Treasurer.

December 15, 1893.

To the Council of The New York Academy of Medicine:

Gentlemen: We have this day examined the accounts of your Treasurer, Dr. O. B. Douglas, and vouchers therefor, and have found them correct.

Charles A. Leale,
Daniel Lewis,
Auditing Committee.

December 15, 1893.

Trustees' Report.—Report of the Treasurer of the Trustees of the New York Academy of Medicine, for the year ending December 31, 1893.

The General Permanent Fund.
(Established by Gifts and Bequests.)

Principal	$11,900.00	
The income of this fund for year 1893 is		$544.24
Balance left from last year		284.28
		$828.52
Transferred to the Building Fund		535.50
Balance		$293.02

Library Fund.
(Established by Gifts, Bequests and Sale of Triplicate Books.)

Principal	$6,282.95	
Increase by sale of triplicates, books, etc.	29.32	
	$6,312.27	
Income of this fund for year 1893		$275.86
Balance left from last year		14.01
		$289.87
Used for purchase of books		228.66
Balance		$61.21

Philippine Meyer and Ernst Jacobi Library Fund.
(Established by gift of Dr. A. Jacobi and Mr. Jacob Meyer.)

Principal	$5,000.00	
Increase by gift of Dr. A. Jacobi	35.00	
	$5,035.00	
The income of this fund for year 1893 is		$225.35
Balance left from last year		3.51
		$228.86
Used for the purchase of books		222.43
Balance		$6.43

HORACE PUTNAM FARNHAM, M.D., LIBRARY FUND.

(Established by Mrs. Eliza C. Farnham in memory of her husband, the late Dr. Horace Putnam Farnham.)

Principal	$10,000.00	
The income of this fund for year 1893 is		450.00
Balance left from last year		95.86
		545.86
Used for purchase of books		514.27
Balance		$31.59

ERNST KRACKOWIZER PRIZE FUND.

(Established by generous gifts of friends of late Dr. Ernst Krackowizer.)

Principal	$1,323.95	
The income of the fund for 1893 is		59.40
Balance left from last year		57.37
Balance		$116.77

The income is available every third year as an award for an essay. If not awarded, the interest of the three years is added to principal.

CARPENTER LECTURESHIP FUND.

(Established by legacy of Dr. Wesley M. Carpenter.)

Principal	$5,813.09	
The income of this fund for year 1893 is		174 39
Paid to the lecturer for 1893		174.39

THE BUILDING FUND.

(This fund is composed of subscriptions or bequests given for the purpose, and of the initiation fees of new members.)

Balance, December 31, 1892		$1,315.95
Transferred from General Permanent Fund		535.50
Transferred from current cash account		2,000.00
Subscriptions		19,776.97
Initiation fees		1,100.00
		$24,728.42
Paid for redeeming 40 bonds at $500	$20,000.00	
Paid for redeeming coupons	1,012.50	
Paid Treasurer of Academy	1,500.00	
Paid for improvements on building	31.00	
Balance		$22,543.50
		$2,184.92

CURRENT CASH ACCOUNT.

Balance on hand December 31, 1892		$544.32
Received from rent of rooms		2,720 00
Received of Dr. Robert Abbe (gift to the Library Fund)		174.39
		$3,438.71
Paid for repairs on building	$81.24	
" water tax	327.60	
" rent of safe deposit box	5.90	
" insurance	177.50	
" collector's services	7.50	
" sundries	21.35	
Transferred to Building Fund	2,000.00	
		2,621.09
		$817.62

The Insurance against Fire upon the Properties of the Academy is as follows:

On the Academy Building	$50,000 00
" books, furniture, etc.	20,000.00
" boilers	30.000.00
	$100,000.00

Respectfully submitted,
W. F. CUSHMAN, M.D.,
Treasurer of the Trustees.

NEW YORK, December 21, 1893

We have this day examined vouchers and balances, also cancelled bonds and coupons, and find them to be as stated in the report of the Treasurer of the Trustees. We also find that there are twenty (20) bonds of $500 each now outstanding.

DANIEL LEWIS,
GOUVERNEUR M. SMITH,
Auditing Committee.

Report of the Library Committee.—The Secretary read the annual Report of Dr. Edward S. Peck, Executive Librarian of the Academy. The Committee on Library has had eleven meetings during the year, none being held during August.

The following donations have been received during 1893, the names of donors having been published at the regular monthly meetings of the Academy: 1,507 volumes, 1,350 pamphlets, 51,780 numbers of medical journals. Purchases have been made from the "Library Fund," "The Phillipine Meyer and Ernst Jacobi Library Fund," "The Horace Putnam Farnham, M.D., Library Fund," and the appropriation of $3,600, voted by the Academy in December, 1892.

The interest of the Library Fund amounted to: accrued interest, $14 01; current interest, $275.86. This was entirely expended in the purchase of 68 volumes. The interest of the Phillipine Meyer and Ernst Jacobi Library Fund amounted to: accrued interest, $3.51; current interest, $225.35. This was entirely expended in the purchase of 85 volumes. This fund has been increased by the addition of $35, through the instrumentality of Dr. A. Jacobi, by vote of the Council. The interest of the Horace Putnam Farnham, M.D., Library Fund amounted to: accrued interest, $95.86; current interest, $450, and was entirely expended in the purchase of 130 volumes. From the Academy appropriation of $3,600, there were purchased 29 volumes, and 200 volumes of medical journals to complete files. Bills for binding amounted to $1,490.30; the remainder of the appropriation was expended in subscriptions to journals, while a small balance was used for miscellaneous sundries.

There have been ordered (not yet received) missing numbers to complete files of journals, at a cost of about $325, bills for which are payable after the beginning of the new year. During the year 44 additional journals have been subscribed for, which makes the current subscriptions to journals, 401. It has been the policy of the Committee on Library not only to subscribe for new American and foreign journals, adjudged the best in their various lines of work, but also to complete old files.

Several discontinued journals have been bought on account of their value for reference work. In those instances where such journals commanded a high price, a rivalry of sale has been instituted, whereby this Academy has been the gainer.

One thousand eight hundred and seventy-nine volumes have been added to the Reference Library during the year. The total number of journals, transactions, and reports on file is 626. The Library contains in the main, or Reference Department, 28,480 books; and in the Duplicate Department, 12,760 books.

In 1893 there were recorded the names of 6,976 readers in the "Visitors' Book"—a daily average of 24.1 for 289 reading days.

The "Want Book" is proving a growing means of expression of the necessities of the readers; and so far as the Library Committee deemed it expedient, each want, after a thorough search on the part of a member designated thereto, was promptly disposed of, with due regard to expense. Under the head of "Wants," Journals, Transactions, and Serials of Researches took precedence of Text Books.

At the October meeting of the Council, it was unanimously voted to enlarge the stack accommodations of the main Library, according to plans recommended by the Library Committee in 1892 and 1893. These plans have been in successful operation in the National Medical Library in Washington, the State Library in Albany, and the State Library in Montpelier, Vt. An appropriation of $5,200 was voted by the Council, and it is contemplated to furnish the new stacking in August, 1894.

The Library Committee suggests, in this connection, that the day is not far distant when new galleries must be erected in the large and beautiful room of the Reference Library, in view of its rapid growth.

The Committee asked for an appropriation of $4,000

for the Library for 1894, basing its estimate on the following:

Subscriptions to journals	$1,500.
Binding journals	800.
Binding reference books	500.
Completing files	950.
Sundries	250.
Total	$4,000.

The Committee recommended with emphasis that the Sections early make known the publications which they desire to be added to the Reference Library. In certain instances of "Wants," several weeks must elapse before a publication can be procured; and to be efficient a Reference Library should be as full as possible.

The Executive Librarian congratulates the Academy on the complete harmony of work between the members of the Committee, and the perfect accord existing between the Committee and the Resident Librarian and his working staff. After some discussion the Report was accepted, and its recommendations were adopted.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 25, 1893.

SENECA D. POWELL, M.D., PRESIDENT, IN THE CHAIR.

Standing Committees.—THE PRESIDENT made the following appointments on standing committees, the appointments being afterward approved by the Society: *Committee on Ethics:* William M. Polk, chairman; S. S. Burt, Arthur M. Jacobus, W. H. Katzenbach, A. Norton Brockway. *On Hygiene:* William A. Ewing, chairman; J. B. Bissell, Edward N. Liell, Herman J. Boldt, Theodore K. Tuthill. *On Prize Essays:* Joseph D. Bryant, chairman; Graeme M. Hammond, Virgil P. Gibney. *Auditing Committee:* James E. H. Nichols, chairman; Carl Beck.

A New Electrode for the Better Utilization of Currents of High Tension.—DR. A. D. ROCKWELL exhibited a new electrode for the better utilization of currents of high tension, and related an illustrative case. When it became desirable to influence by the galvanic current internal organs or portions of the body deeply seated, currents were required of far greater strength than could be employed by the usual electrodes without causing excessive pain in the skin. Of the various materials with which the metal plate of the electrode had been lined, he knew of none so satisfactory in overcoming the resistance in the skin to the passage of the current as potter's clay. The objection to this had been that it was dirty and difficult to handle without soiling the clothes. To overcome this objection and to enable one to make use of clay as the most valuable material when powerful currents were to be used, he had devised the instrument presented. It consisted of a shallow cup or disk made of non-conducting material (hard rubber), the bottom or inside covered with block tin to resist oxidation. The cup was filled with the clay. One two inches in diameter would easily conduct through the skin seventy-five milliampères without pain. The one exhibited was circular, five inches in diameter, and would distribute the current over a large area.

The illustrative case was one in which the diagnosis of cancer of the kidney had been made by Dr. Bryant, confirmed by Dr. Janeway, also, after urinalysis, by Dr. Biggs; an autopsy was not obtained. The woman had suffered excruciating pain day and night for four months, opium and other agents failing to give relief, until Dr. Rockwell tried strong galvanic currents, increasing from 75 to 150 milliampères, applied with the new clay electrode five inches in diameter, one over the tumor, the other under the left shoulder-blade. Pain then disappeared, for the first time in some months; mild currents had no effect. The pain of scirrhous cancer of the breast was sometimes relieved by currents of far less strength.

DR. JOSEPH D. BRYANT, who had been given the credit by Dr. Rockwell for making the diagnosis of cancer of the kidney in his case, was called upon. The diagnosis, he said, was not very difficult. The general appearance of the patient pointed to some organic change, probably of malignant character. A tumor was felt, and the question to be decided was whether it involved the spleen, kidney, or other parts including the abdominal walls. The spleen seemed on percussion to be in its proper place and of normal size, and as there was some tympanitic resonance over the tumor, the abdominal walls could not have been involved by it. Ordinary urinalysis showed nothing abnormal, until Dr. Biggs sought for cholesterin and found it. It was the second case in which Dr. Biggs had found cholesterin in malignant disease of the kidneys, and he at once regarded it as pointing with reasonable certainty to malignant disease, probably of cystic character. Unfortunately no autopsy was obtained.

A New Agent in the Treatment of Epilepsy.—DR. PAUL GIBIER presented a second contribution to the treatment of epilepsy by injections of a nervous (cerebral) extract, his first paper having been read about a year ago, a brief abstract of which was published at the time in the MEDICAL RECORD. Since then he had continued his observations upon the old cases, and had added new ones. The new ones, which had been markedly improved under the new agent, were about nine in number, of which he read a brief history. Four others which had been submitted to the treatment, had not done any better than they had formerly done under bromides, and therefore the treatment was discontinued. Of the older cases he continued the history of two, both of which had been under treatment about eighteen months, the improvement, very striking in one, having persisted as long as the injections were kept up. Most of the cases gave a history of grand mal existing several years or from infancy, and in all, excepting the four already mentioned, the improvement had been marked, the grand mal, as a rule, having been converted into petit mal, the attacks appearing at longer intervals, the bodily and mental condition also showing improvement.

DR. W. M. LESZYNSKY inquired whether the new treatment had been accompanied by a change of diet, hygiene, and medication. Almost any new remedy (antispasmodic) would reduce the number of attacks for a while, especially when accompanied by regulation of the diet and hygiene.

DR. SPRATLING inquired whether the author had a theory for the action of his remedy.

DR. GIBIER replied to the first inquiry, that as a rule he did not neglect the diet of the patient in epilepsy, nor in other diseases; yet in most of the cases reported the patients lived outside, and he had no control over their mode of living. In some of the cases the bromides were stopped entirely. Regarding the mode of action of the remedy, theoretically one might suppose the nervous substance which was injected supplied a want in the nervous centres from which the epileptic attacks started, and enabled them to resist the discharge. Of course, as long as we remained ignorant of the nature of essential epilepsy, any explanation of a remedy would be only hypothetical.

A New Disease of the Vagina—Peri-vaginitis Simplex.—DR. J. J. E. MAHER read a paper bearing this title. While the observation of a single case could not be all that was desired in establishing a new disease, yet the one which he had to report seemed to be unique, and, in his opinion, justified the diagnosis of a new disease, peri vaginitis simplex. The patient was a primipara, twenty-three years of age, had been married a year, had been delivered nine days before Dr. Maher was called, forceps having been used. Hemorrhage continued after delivery for about three days, being more or less checked by ergot, etc. Her physician then told her she could get up, but she tried this two or more days in succession, but was prevented by intense pain about the perineum. When Dr. Maher was called on the ninth day there was slight hemorrhage, the patient was pale

and weak, the pulse 120, temperature 100° F., skin clammy; tongue clean; pain about the perineum; the entire perineal body of bony hardness and presenting a laceration of about a centimetre, with thickened, everted lips which could not be easily approximated. When the labia were separated the vagina beyond was seen as a rigid tube, the cervix uteri being distinctly visible at the upper end as if observed through a speculum. Pressure on the perineum felt to the patient like sitting on a hard ball, and caused intense pain. The uterus was not painful. The mucous membrane of the vagina appeared normal. After a few days treatment the induration disappeared, the vaginal walls collapsed, disagreeable symptoms ceased, the lesion of the perineum was the only pathological condition left. When Dr. Maher saw the patient the stools were liquid but foul, and her mother said there had previously been constipation for which oil was given, causing extremely malodorous movements. In view of this fact, pointing to distention of the rectum with hard fæces over which the child's head had to pass, and of limitation of the symptoms in the immediate vicinity of the vagina, absence of general septic symptoms, presence of pain at both ends of the rigid vaginal tube, and certain other facts in the history, the author made the diagnosis of peri vaginitis simplex or simple inflammation of the tissue surrounding the vagina, and depending upon over distention. Distention of the vagina beyond physiological bounds under ordinary circumstances might be impossible, but it seemed not impossible, and to really have taken place in this case, where there also existed distention of the gut behind it from fæces driven before the child's head. Before commencing treatment he could easily recognize increased thickening of the recto-vaginal cellular tissue as it was felt between the fingers, one in the rectum and the other in the vagina. The author differentiated the condition from peri-vaginal œdema.

The prognosis was favorable if treatment were instituted in time to prevent necrotic changes.

Clinical Department.

SUBACUTE ARTHRO SYNOVITIS IN AN INFANT, CURED BY A PLASTER-OF-PARIS SPLINT.

By GEORGE D. FARWELL, M.D.,

TURNERS FALLS, MASS.

Harry G——, aged two years and two months, brought to me December 1st, with the following history: Mother has had acute rheumatism twice, now healthy. Her parents had rheumatism. Infant (only child) healthy up to four weeks ago, when, in attempting to climb to window-sill, fell, striking left knee upon a slanting surface of about forty-five degrees

Next day child limped, and became gradually worse up to the present time, December 1st. Examination shows knee markedly swollen symmetrically. Palpation shows some superfluous fluid in the joint. Knee not markedly tender on pressure. Considerable tenderness upon upward pressure of tibia. Examination for hip-joint disease, negative. When sitting, extensors of foot are in tonic contraction. Examination of ankle, negative. Temperature of left knee, slightly elevated as compared with right. In walking, infant halts, extends the left leg upon the thigh with apparent difficulty, and with what might be termed a "wooden-leg finish," then places left foot very lightly upon the floor, makes a short step, and comes down on the right foot with a thud.

December 2d.—Knee, thigh, and leg enveloped in a thin layer of cotton; flannel bandages applied, and plaster of Paris splint over that. Plaster not hardening rapidly owing to slight misunderstanding about baking it by mother, wooden splints covered with cotton were applied over the plaster-of Paris. Tongue somewhat coated. Hydrarg. chlor. mitis cathartic given, also a mild diuretic of potas. cit. and spt. ætheris nit.

December 3d.—Plaster splint hardened nicely.

December 6th.—Splint slightly looser than on 3d, undoubtedly on account of reduction of swelling. Child is somewhat anæmic. Ol. morrhuæ prescribed.

December 8th.—Lower extremity of splint somewhat broken and crumbled; splint dropped down slightly; was accordingly pulled down over the foot, and removed. Child afraid to walk alone, but walks without limping, with mother holding hand.

December 9th.—No limping.

December 13th.—Child walks alone without limping or halting. Has had no limping, tenderness, nor swelling since splint removed.

THE AWAKENING EFFECT OF COCAINE.

By JOSEPH WILLIAM STICKLER, M.D.,

ORANGE, N. J.

A few days ago a patient who had toothache, wishing to stop it immediately, secured nine grains of cocaine in solution, and took it into his mouth a little at a time, holding it till the accumulation of saliva became so abundant that he had to spit it out. He began using the cocaine in this manner at 5 P.M., and did not cease till 10.22 P.M., same evening. As it was then bed time, he thought he would make sleep certain by taking twenty grains of chloral. Immediately after taking the latter drug, he took into his mouth some more cocaine, and went to bed. He "swashed" the cocaine solution about in his mouth awhile, then spat it out, turned on his side and tried to go to sleep. Sleep, however, did not come; on the contrary, he did not even become drowsy. Having lain awake till midnight, and not feeling sleepy at that hour, he took, as nearly as he could tell, about *one teaspoonful* of laudanum. He went to bed again and remained awake till three o'clock. Sleep lasted only four hours. Following this was headache.

I have often had my attention called to the fact that cocaine will keep patients awake at night, when the drug is administered late in the day, but I did not know that twenty grains of chloral and a teaspoonful of laudanum would not overcome "cocaine wakefulness."

A CASE OF DIABETIC MULTIPLE PERIPHERAL NEURITIS.

By A. REICH, M.D.,

NEW YORK.

John C——, sixty-three years of age, born in Madeira; lived for the last forty-three years in Bermuda; engaged in liquor business since fifteen years; before that he was a butcher and farmer. He travelled all over the southern part of Asia, and Europe, and northern part of Africa. Family history is of no importance. His habits are moderate, smokes, does not chew, never indulged in sexual excess. Has children by first wife, all healthy; no children by second wife (a sufferer from fibroid of uterus and metrorrhagia). He is well built, stands five feet five inches, weighs one hundred and seventy pounds stripped; is intelligent looking. He was healthy except for an attack of yellow fever until four months ago, when he was taken with severe vomiting and diarrhœa lasting four to five days. Soon after this he noticed some numbness in tips of his fingers and toes, accompanied by formication and weakness. At the same time polydipsia set in and he had to get up nights to pass water more than once (hypertrophied prostate). Two months passed and now shooting pains along the course of the nerves of the upper and lower extremities were noticed, which extended in a central direction and were worse at night. He also complained of coldness in extremities and wore gloves constantly. He passed about eight pints of urine in twenty-four hours, specific gravity 1.035, containing no albumin,

but showing eight per cent. of sugar. Lost thirty-five pounds in four months.

Examination. — Internal organs normal. Eyes and ears normal. His extremities seem to be of normal temperature. The finger-nails had a brownish discoloration and were unusually longitudinally striated. The skin over the roots of the nails and first phalanges appeared puffy and shining, the remaining skin was normal. All the fingers were in slight flexion, thumbs adducted; voluntary apposition of fingers absent, thumb could be apposed with every finger except little finger. He could flex wrist, but not extend it. Flexors of elbow were weakened, also the deltoids. Thenar and hypothenar eminences were wasted considerably and also the interossei muscles. Extensors and flexors of wrist were very flabby and wasted. Flexors of elbow were somewhat wasted; same also with deltoids. Triceps was well preserved, sensation; tactile and heat sense was good; there was hyperalgesia, beginning from two inches above wrist and increasing to the tips of fingers on the palmar surface, while on the dorsal surface there was an area of anæsthesia over thumb and hyperalgesia of last two phalanges only.

Lower extremities: Sensation was good, some hyperalgesia below ankle. Anterior tibial and perineal group of muscles somewhat wasted; extension and flexion at ankle fairly good. Muscles of the calf were weakened. Extensors and flexors at the knee were below the normal strength.

Electric reaction: There was reaction of degeneration in all wasted muscles.

Dr. L. Putzel, to whom I express my thanks, was kind enough to examine the patient with me.

341 West Twenty-third Street.

Therapeutic Hints.

Cannabis Indica.—My experience warrants this statement: Cannabis indica is, often, a safe and successful anodyne and hypnotic.—Mattison.

Dyspnœa of Acute Phthisis.—Dr. Bernheim (*Deutsche Med. Wochenschrift*, No. 37, 1893) recommends in the dyspnœa of acute phthisis the following formula:

℞. Caffeine citrate..... 2 gram. (grs. xxx.)
Sulphuric ether..... 20 gram. (℥ v.)
Inject two grains (30 gtts.) morning and evening.

Onychomycosis.—Confusion in diagnosis is more likely with psoriasis and primitive eczema than with central nervous disturbances which would have concomitant symptoms. The microscope must be used in any nail disease before positive diagnosis is made. It is an extremely persistent affection and may last a lifetime without much change. The nail may be torn off, or, under close watching, an active inflammation of the matrix set up with pyrogallic acid and olive-oil, equal parts.—Dubreuilh.

La Grippe.—Sulphite of sodium, 5 grains, every two hours.

℞. Sodii sulphit..... ℥ iv.
Aquæ..... f℥ vj.

M. S.: A teaspoonful in as much water every two hours till all pain is relieved and the patient is well.

—Monell.

Sciatica and other neuralgias.—

℞. Tinct. aconit.,
Tinct. colch. sem.,
Tinct. bel.,
Tinct. actea racem.....āā equal parts.
S.: Six drops every six hours.

—Metcalf.

Theobromin (gr. 45 to 75 daily for three days) gave good results in grave cases of cardiac dropsy.—Germain Sée.

Strophanthus is much more rapid in its action than digitalis, but is not suitable for prolonged use. In one case, in which during three or four days its good effect was conspicuous, the heart, under its prolonged use, became extremely frequent and the sense of cardiac distress extreme; and yet, when its employment was entirely given up for a week, it proved as rapidly and as distinctly useful as before.—Little.

Toothache.—

℞. Dry alcoholic extract opium,
Camphor..... āā 0.50
Balsam Peru,
Mastic.....āā 1.0
Chloroform..... 10.0

Introduced into the cavity it calms the pain at once.—*Jour. de Pharm.*

Acetate of Aluminium is, next to carbolic and salicylic, the disinfectant which prevents, for the longest time, the development of micrococci and produces no irritation.—Fraipont.

Caffein, I think, deserves to rank next as a cardiac tonic. I have, in a few cases, got undoubted help from it. They were all old cases in which digitalis and strophanthus had ceased to benefit; they were all aged persons; they were all short of breath and dropsical, and presented the signs of dilatation with degeneration of the ventricular walls.—Little.

Locally for Joint Rheumatism.—

℞. Acid. salicylic..... ℥ jss.
Alcohol. absolut..... f℥ j.
M. Olei ricini..... f℥ ij.

By compress covered with impermeable tissue.—Ruel.

Camphor Solution for Hypodermic Injection.—

Camphor..... 2.0
Liquid paraffine..... 8.0

A one gramme syringe will contain twenty centigrammes of camphor.—Bosner.

Chloride of Gold and Sodium in pills or granules, given in dose from two milligrammes to three centigrammes improved the general condition of paralytics in the first and second periods.—Boubila.

Appendicitis.—The majority of so-called recoveries, treated medically, are not recoveries in the full sense of the word, but simply a respite which enables one to settle worldly affairs and take out a life-insurance policy in anticipation of a fatal termination.—Sanborn.

Piperazine.—Piperazine is perfectly harmless. In birds deposits of urates can almost with certainty be produced by neutral chromate of potash. In the majority of cases piperazine prevents the deposition of urates produced by the chromate, while lithium carbonate, borax, and sodium phosphate are powerless to prevent it. These experiments confirm the results of treatment of the uric-acid diathesis by piperazine.—Biesenthal.

Epilatory Liquid.—

℞. Pure iodine..... grs. xii.
Essence of turpentine..... ♏ xx.
Castor-oil..... f℥ ss.
Alcohol..... f℥ iiss.
Collodion..... f℥ j.

M. Sig.: Apply once daily for three or four days. When the collodion comes away, a clean surface will be left.

Asthma.—A capsule containing two grains of phenacetine, one of quinine, three of muriate of ammonia, one-eighth of capsicum, and one twenty-fourth of strychnine, given four times daily, will often relieve an attack of this distressing malady.—Mays.

Emphysema.—

℞. Essence of turpentine..... 4–5 gram.
Peppermint water..... 120 gram.
Sugar,
Pulv. gum acacia.....āā 4 grams.

M. S.: Dessertspoonful every two or three hours.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

DIPHTHERIA OF THE STOMACH—LARYNGEAL GROWTHS—BENIGN AND MALIGNANT—TOOTH-BEARING DERMOIDS—ABSCESSES IN CONNECTION WITH THE ŒSOPHAGUS—INFLUENZA INCREASING—DEATHS OF DR. TILT AND DR. CORNER.

LONDON, December 23, 1893.

THE brief Christmas recess has begun, and a quiet week will be grateful to those who have been hard at work in the hospitals and societies.

On the 19th there were some interesting specimens at the Pathological Society. One of these was a specimen of diphtheria of the stomach from a child of three years which was admitted to hospital for croup. There had been complete anorexia, and food administered by a tube was invariably vomited—the vomited matter giving no trace of hydrochloric acid. Tracheotomy became necessary, but the child died the day after. At the autopsy, membrane was found in the larynx and extended downward into the finer bronchi. The pharynx and œsophagus were full, but the whole of the stomach was lined with exudation which extended for a third of an inch through the pylorus. The clinical feature of this case, complete anorexia and rejection of food administered, is interesting, as the implication of the stomach is so rare and here the entire lining was affected.

Another specimen was a tooth-bearing dermoid removed from the cheek of a boy of five years. Beneath the erupted tooth was a small permanent tooth, a circumstance very noteworthy in the rare case of true superficial dermoids.

The sequel of a case of laryngeal tumor formerly related was reported, and gave rise to some renewal of the question whether benign growths can become malignant. In the case in question, at first it was supposed to be a papilloma with a tendency to hemorrhage, but the sequel proved it to be of a malignant nature; and it would seem to have been so from the beginning, for it resembled more than anything duct-carcinoma of the breast. It had recurred four months after operation, and was larger than ever in about six weeks. It was again removed by the galvano-caustic loop, and the microscopic appearances were now unequivocal. Sub-hyoid pharyngotomy was then performed and the growth removed. There was slight secondary hemorrhage the first day. Otherwise all went well until the evening of the third day, when the patient became suddenly unconscious, the temperature rose to 105° F., with deep coma and Cheyne-Stokes's respiration, and he died next morning. The autopsy showed congestion of the brain and œdema, but there was nothing to show the immediate cause. The question whether irritating innocent growths provoked malignancy was referred to by several speakers, most of whom repudiated the notion, and one surgeon thought it beneath the dignity of the Society to discuss, for the supposed cases were vitiated by the probability of clinical error. This is true enough, but by no means surprising so far as the larynx is concerned, for a glance at the reflection of one surface of a growth is a very different thing from the opportunity of seeing and handling which surgeons enjoy in the case of so many external tumors. The specimen was referred to the Morbid Growths Committee.

Three specimens of abscess in connection with the gullet were exhibited—one was on the side of the neck and discharged into the gullet, and proved fatal by eroding the inferior thyroid artery; another seemed due to a stricture from corrosive poison taken thirty-three years before; and the third to suppuration in posterior mediastinum around the lower third of the œsophagus.

Influenza increases very much and is spreading through country districts. At the London Hospital, a few days ago, 50 of the nurses were laid by with this disease. No less than 164 deaths were registered last week as influenza, the deaths in the prior four weeks being 127, 74, 36 and 22. The whole class of respiratory diseases is giving an increased mortality, and no doubt the epidemic is to blame for this. Considering the innumerable cases which run a favorable course, the returns show that an enormous amount of illness must prevail.

The death of Dr. E. J. Tilt occurred on December 17th, at Hastings, from cerebral hemorrhage. His "Uterine Therapeutics" and his "Change of Life," as well as perhaps some of his other books, will be well known to your readers. He was a past president of the Obstetrical and a fellow of several other societies, and a Knight of the Crown of Italy.

Dr. Matthew Corner, who has done much good work as a sanitarian at the East End, died on December 7th. He worked hard in the cholera epidemic of 1866, which was so serious at the East End, and has continued to remain in that district until the close of his useful life. For the last few years he has been in delicate health.

NEW AND RAPID METHOD OF ANÆSTHESIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In reply to my communication of a "New and Rapid Method of Anæsthesia" (MEDICAL RECORD, October 21, 1893, page 524), Dr. Rugh, of Philadelphia, in a letter published in the issue of the MEDICAL RECORD for November 18, 1893, disputes my right of "priority" by the statement that the process which I described was employed in the United States thirteen years ago. This letter was brought to my notice to-day, and I reply immediately.

In the course of our experiments with this new method Dr. Bourbon and I judged it necessary to make a complete study of anæsthesia for which ethyl bromide was employed, and we have, I think, a complete bibliography of the subject. The articles which treat this subject—about three hundred in number, published in English, French, German, Russian, Italian, and Spanish—have with few exceptions—publications inaccessible at Paris—been completely examined by us. The authorities cited by Dr. Rugh are noted in our bibliographical list: one of them is inaccessible here, but from its indications I question that this author in any way mentions a combined process of anæsthesia by ethyl bromide continued by chloroform. The other indications of Dr. Rugh I have verified this afternoon, and find that the authors treat of anæsthesia by ethyl bromide alone, a process which differs essentially in application and possibilities from that which I describe. These authorities of Dr. Rugh say not one word of the use of chloroform.

In our bibliographical research (Dr. Bourbon and I)—in six languages—we have not found a single mention of an anæsthesia by the method described, which belongs to an American operator. I have to thank Dr. Rugh for the courteous tone of his letter and the value which he accords to this process; but finding that the articles indicated by him and accessible to me in no way mention this method of anæsthesia, I fear that my disputant is led by our use of ethyl bromide to the conclusion that my "priority" was "pretended;" for anæsthesia induced by ethyl bromide alone, a perusal of my article will show that no such deduction is permissible.

Should Dr. Rugh be able to refer me to a single published report of an anæsthesia performed in accordance with the method I describe, by an American surgeon, prior to August, 1892—date of our first experiments—I shall be personally indebted to him for the "Honor to whom honor is due," but until then maintain my assertion to have been the first American to employ this new and rapid method of anæsthesia.

Will you allow me, in addition to my communication of October 21st, to invite attention to the utility of this method for the abortive treatment of convulsive attacks in eclampsia, epilepsy, and hysteria. The rapid action of the ethyl bromide—abolition of reflex action in thirty

to sixty seconds—serves frequently to abort completely the convulsion, and in case of persistence of the tendency to convulsions (subintrans) the continuance of the anæsthesia with chloroform prolongs the therapeutical action *ad lib.*

Theoretically, the stimulus of the salivary and sudoral glands (organs of elimination) exercised by the inhalation of ethyl bromide, should be particularly useful in eclampsia and other convulsions of toxic origin.

Yours truly,

WILLIAM S. MAGILL.

ÉCOLE DE MÉDECINE, PARIS, FRANCE,
December 18, 1893.

THE SILENT MAJORITY IN THE MEDICAL PROFESSION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The fact must impress all careful observers of current medical literature and of the proceedings of our great societies, that the mass of the profession is never heard from. That this is a serious hinderance to the great object of all such activity—the search after truth—no one can doubt. How often does the average general practitioner listen to the special pleading of some young congenial specialist with the feeling that it is error and not truth that is gaining the prestige of publication from the forum of an influential society. That which is not true is false, and half truth is falsehood's most dangerous shape. The common knowledge of the profession should be the court of final appeal in questions of medical truth. Most cases of appendicitis never reach the operating and publishing surgeon, and yet what must be the opinion formed of this lately fashionable complaint, if formed from current literature. But how can the day be hastened when every man will form and express an opinion on every point.

A reaction against specialism and toward generalism in practice of medicine has set in. Let this be encouraged.

Encourage the discussion of all points in general medical meetings, attended by men able to see from all points of view. Compel an opinion from all present by demanding a vote from all present as to the absolute truth in the case of each point under discussion.

Questions can be formulated so as to make such expression of exceeding value, and by this means and by no other can we obtain the common knowledge of the profession lying dormant in the silent majority.

LOUIS FAUGÈRES BISHOP, M.D.

36 WEST THIRTY-FIFTH STREET.

MECHANICAL VIBRATION IN THE TREATMENT OF DISEASE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of the MEDICAL RECORD dated November 25th, under "The Practitioners' Society of New York," the President, Dr. Chas. L. Dana, under the heading "Mechanical Vibration in the Treatment of Disease," describing some apparatus made by a Paris electrician, makes several statements which I would not like to see pass uncorrected.

Vibrations as a therapeutic agent came into use, not as Dr. Dana states, "twelve years ago," but in the beginning of the century, and were extensively practised in Sweden by the gifted layman Pehr Henrik Ling and his pupils, who applied them manually.

In 1865, Dr. Gustaf Zander, of Stockholm, the founder of modern scientific mechanico-therapeutics, among many active, passive, and orthopedic apparatuses for the exercise of different parts of the body, invented apparatuses for general and special vibrations which he classifies among the series "Apparatuses for mechanical operations, *i.e.*, vibrations, percussions, kneading, rolling, friction, etc." The motive power of these apparatuses is a gas, steam, or electric motor.

The apparatus for special vibrations, Fig. 1, can be applied very rapidly and very powerfully, but like all of Dr. Zander's apparatuses, it can be individualized and graduated according to need. It can also be applied less powerfully and gently. This apparatus responds to all demands of well-informed physicians and physiologists.

Vibrations were never considered by Dr. Zander nor his pupils as a separate method of treatment, but in cases in which vibrations are indicated, they form an integral part of the whole mechanico therapeutic treatment plan.

Dr. Mortimer Granville published "Nerve-vibration as a Therapeutic Agent," *Lancet*, 1882. "A Note on the Treatment of Locomotor Ataxy by Precise Nerve-vibration," *British Medical Journal*, 1882, and his book on "Nerve-vibration and Excitation," London, 1883.

Will Dr. Chas. L. Dana kindly name the "Swedish physician" who, "a little later" (after Granville) "devised a machine which was operated by a crank, so that very powerful, though not very rapid, vibrations could be produced in different parts of the body?"

L. WISCHNEWETZKY, M.D.

NEW YORK, 9, 11, 13, EAST FIFTY-NINTH STREET.

THE MEDICAL PROFESSION AND THE HOSPITALS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The immense influence exerted upon professional thought by the MEDICAL RECORD not only throws upon you a grave responsibility in respect to every line of your editorial utterances, but also makes it the duty of your readers to criticise the latter when the remarks of a less important journal would be unworthy of notice. It is because of my respect for the MEDICAL RECORD that I call attention to the editorial with the above title, which appeared in your issue for January 6, 1894.

When you speak of the relations existing between the managers of hospitals and the medical staff, it seems to me that you do not present the case quite fairly. Passing over the colloquial use of the word "always" in the sentence which alleges that "the treatment of medical men by hospital managers has *always* been arbitrary," etc., where the idea to be conveyed is evidently not quite so sweeping as the sentence implies, I must protest against your expressions which immediately follow, and which can only be interpreted to mean that you think it unjust for the managers to accept the services of the medical staff without pecuniary compensation, and to admit relatively wealthy people to private rooms without insisting that the medical man in attendance receive pay for the care of such people.

You say that the theory that hospital physicians should not be paid for their work because there are men enough willing to do the work without pay, "has a certain economic basis, we admit, but is not an absolute one, otherwise why should it not be applied to positions of honor everywhere?" and you mention the custom of paying congressmen, judges, etc., as though there were a very close resemblance between the cases of these officials and the medical staff of hospitals. I do not see that this is so. The reason that congressmen and other officials are paid is, that it has been found, by experience, impossible to get the work for which they are selected done as well without pay as it is when the pay is provided. It is not found to be so with hospital doctors.

In the case of hospital managers, the conditions of the trust which they administer demand that they obtain the best medical service possible. If this can be accomplished without paying the doctors, they have no right to pay them; if they should do so, they would be guilty of wasting trust-money. If the best service cannot be obtained without pay, the managers should pay as little as is compatible with effecting the desired result. The managers have no duty other than the administration of the property committed to their charge in such manner

as to make that property useful for the purpose for which it is intended. Moreover, they must try to make every cent thereof exert its full power. If the doctors are willing to work without that cent, they ought not to give it to the doctors. Of course, it will be understood that I allude always to medical men capable of doing the best kind of work. Do you, Mr. Editor, or does anyone, think that the quality of medical talent at the service of the hospitals of this city would be improved, or that the patients in these institutions would receive better care, if a money compensation were offered? If so, what sum of money would be needed to accomplish this desirable result? If not, what right have the managers to offer any? The law of supply and demand decides this as well as all other economic questions; the precise market value of hospital attending physicians and surgeons is unquestionably represented by the amount which can be obtained by them in the face of competition—that is to say, at the present time its value is nothing more than the personal advantages gained by them in other than financial ways.

The same reasoning applies to the treatment of patients in private rooms. If the managers, for the purpose of increasing the institution's income, think best to provide for such a class of patients, medical men cannot object to complying with their wishes, unless the doctors happen to be so situated as to be able to practically "corner" the medical labor market. In some hospitals the medical attendant is allowed to charge for his services; if he so arranges with the occupant of a private room, but this is a privilege, not a right.

That the relations between the managers and medical staff of most hospitals are more or less strained is undeniable; but it appears possible that in this respect the doctors are not blameless; whether or not the former regard "the medical staff as a kind of necessary evil," the latter are too apt so to regard the managing board. Are not both sides to a certain extent right? Is there not a good deal of needless friction in hospitals because of the rather hostile attitude of the professional and lay officers?

J. West Roosevelt, M.D.

New York, January 8, 1894.

[We cheerfully admit the truth of the facts so courteously presented by our esteemed correspondent, although we still beg to differ from some of his conclusions. We cannot see why, even for the sacred trust imposed upon the goodly manager, that wealthy people able to pay hotel-rates for board should be treated for nothing. The real business of every public hospital is to treat the poor. There are other interests besides those of the hospitals to be taken into account. How about the hard-working outside practitioner whose rich patient is thus taken from him by the overt and unjust inducements of the managers of the Hospital Trust?—Ed.]

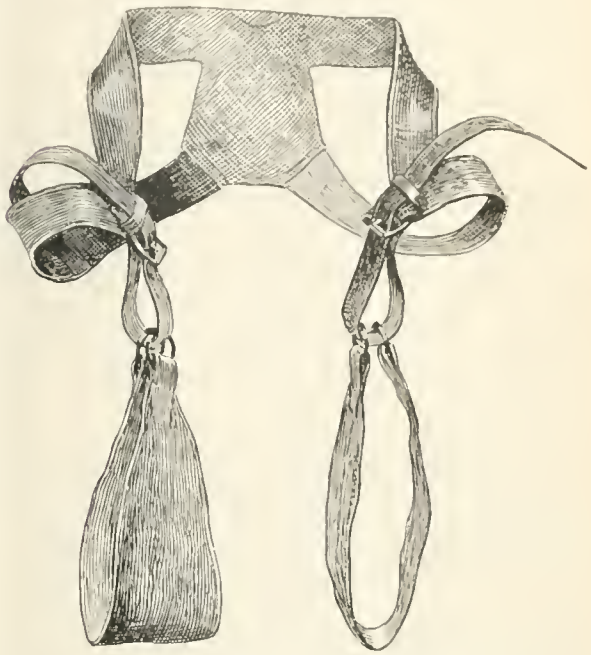
New Instruments.

NEW APPARATUS FOR USE IN OPERATING IN THE PERINEAL REGION.[1]

By J. HENRY DOWD, M.D.,

Buffalo, N. Y.

Being called upon quite frequently to operate on and around the perineal region, and especially where the urethra must be held in the median line, I have tried to devise something which will be handier to carry and also overcome some of the disadvantages of Clover's crutch, or the apparatus known as Blake's, both of which I have used quite frequently.



The advantages I consider are:

1. Pressure is equalized over both shoulders; circulation is not interfered with nor the neck drawn forward, as is caused by the above-named appliances.

2. The legs are held in the median line and are not drawn down to the side under which the strap passes, as with the crutch.

3. It can be carried in a small surgical, or for use in obstetrics in the obstetric, bag.

4. The simplicity, both of the apparatus and its application, can be readily seen by the cut. The patient puts it on the same as a shoulder brace, and no matter how violent they become, it stays in place.

5. The inexpensiveness plays the most important part. Any harnessmaker can construct one in half an hour, or it may be made of cloth at home, the cost being nominal.

[1] Presented at the Surgical Section of the Buffalo Academy of Medicine, December 5, 1893.

Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

The Kind of Insane People that Kill.—The immediate causes of homicides by the insane have been thus outlined by Burdraghi, *Medical Standard*, some years ago: The great majority of homicides by the insane are committed under the influence of persecutory delusions. Eighteen per cent. were associated with epilepsy, and one was anthropophagous. In fifty-eight per cent. the murdered persons were relatives, and in forty-two per cent. strangers. The youngest homicide was only four years of age, a girl who threw into the fire an infant she was left to mind; the oldest was seventy years of age; the majority, thirty, between thirty and forty years. Seventy-five were men, and twenty-five women; seventeen were quite illiterate, and sixty-one very imperfectly educated. Religious delusions were present in twelve, and in five of these were the immediate motive of the crime; twenty-five labored under hallucinations, and fourteen had been previously insane. Fifteen were in-

stances of plural homicides, one individual having perpetrated no fewer than eleven. In nineteen no motive could be assigned. That even excessive joy may subvert the reason is proved by the case of a man who, having unexpectedly come in for a fortune of $10,000,000, killed his wife and children. In fourteen per cent., a surprisingly small proportion, was the act premeditated, and, as in fifteen per cent. of the whole, considerable ingenuity was shown in its execution. Twenty-seven sought concealment in flight, but all sooner or later returned. Three only attempted to prove an alibi. Twenty-three prevaricated, but of these twelve had lost all recollection of their acts, sixty seven remembered them, but in fourteen cases they were committed under the influence of hallucinations; fourteen others, though cognizant of what they had done, were of very weak intellect, and one was a case of transitory frenzy. Fifty four exhibited more or less remorse, but of these forty six failed to realize the heinousness of their crimes; seven gloried in them; twenty-three attempted to exculpate themselves; thirteen, undoubtedly of weak intellect, simulated insanity; eleven of these were subsequently transferred from the asylum to the jail; and six in all succeeded in escaping from asylums.

Loretin, a New Antiseptic.—Schinzinger (*Wien. allgem. med. Zeitung*, No. 47, 1893), after referring to the objections to the use of iodoform, describes a substance which has been equally successful in his experience; its chemical name is "meta-iod ortho oxy-chinolin-ana-sulfonacid," for which the name "loretin" has been substituted. It is an iodine preparation, at the same time possessing the properties of a phenol and the important characteristic attributes of a chinolin derivative. Physically it is a yellowish powder, consisting of minute crystals and resembling iodoform, but having no odor, and only slightly soluble in water or alcohol, but forming useful emulsions with oil, collodion, etc. As a powder it is very serviceable when somewhat diluted, and with metals it forms valuable salts—the calcium salt, for instance, being insoluble in water, and a very suitable substance with which to impregnate gauze. Loretin is non-poisonous, and no untoward effects ever followed its use after operations or for ulcers, etc.

The External Use of Salicylic Acid —Dr. Ruel, of Geneva, recommends the external use of salicylic acid in rheumatism. He says that: 1st. Salicylic acid is rapidly absorbed by the skin. 2d. After so applied, it promptly appears in the urine. 3d. It possesses a positive curative action in rheumatism. He found that the best results were realized when the salt was dissolved in alcohol with about double its volume of castor-oil in the form of a liniment, that has been supplied to our pharmacopœia in years. M. Ruel's customary formula is:

℞. Acidi salicylici.....	20	grammes.
Alcohol absolute.....	100	"
Ol. ricini.....	200	"

This is to be applied on a flannel, which is to be covered with some impermeable material, morning and evening. In certain solutions a small quantity of chloroform may be added—say five per cent. This addition serves as an analgesic; besides, favors the absorption of the medicament. About twenty minutes after the salicylic is so employed it can be found in the urine, and a few minutes after a salicylic liniment is applied pain vanishes, and it is replaced by a sense of warmth and comfort. Olive-oil may be substituted for castor-oil. In lumbago and painful muscular affections, chloroform and opium may be added.

The Proper Use of Esmarch's Bandage.—There has not been much said about Esmarch's bandage of late years. At the last meeting of the German scientists and physicians, Professor Esmarch made his bandage the subject of his address, and endeavored to rehabilitate it somewhat. The objections to its use he said were the following: 1. The free hemorrhage that took place after removal of the elastic bandage from paralysis of the vessels. 2. Paralysis of nerves pressed on by the elastic bandage. 3. Death of flaps of skin, or margins of wounds. 4. The danger of the entrance of septic material, etc., into the circulation.

In spite of the endeavors of the discoverer to improve the method, to simplify it, and to prove that the disadvantages did not depend on the method but on a perverted use of it, these objections were constantly being repeated, and many surgeons were thereby prevented making use of this process. Professor Esmarch thought it, therefore, not without use for the Society to describe the art and method in which artificial bloodlessness had been procured in his clinic for the last fifteen years. The process consisted, as was known, of two parts: The aim was (1) to draw the blood out of the parts to be operated on, and (2) to prevent the flow of arterial blood during the operation. The first aim was accomplished in part by the elastic bandage, and in part by the perpendicular elevation of the limb; the second only in rare cases by the elastic tubing originally recommended, but by an elastic girdle with a very simple hook catch. He enumerated the precautions that had to be observed in the use of the method, and said that if no rules were followed the disadvantages mentioned would never be met with. India-rubber appliances lost their elasticity by long keeping, and also by being kept in hot or cold climates, so that he had introduced elastic bandages made of spiral brass wire, which would remain in good order for years and in any climate. Many lives had been already saved by the timely use of his elastic tourniquet suspenders or braces. The question how long a well-adjusted elastic bandage could be left on in case of arterial hemorrhage, was still an open one. From his own experience it would seem that arterial intercourse could be interrupted without any special injurious consequences for at least twelve hours. In conclusion, he reminded his hearers that the procedure of influencing the current of blood in arteries and veins by elastic pressure, had led to a number of other therapeutic measures, for example, to auto-transfusion, to treatment of pseudo-arthroses and aneurisms, but above all to phlebostasis, discovered by his assistant Dr. Bier, and practised with great success in his wards in the treatment of surgical tuberculosis.

The Massachusetts State Board of Health on the Healthfulness of Artificial Ice.—This Board concludes, from investigations of artificial ice, that artificial processes of freezing concentrates the impurities of the water in the inner core or the portion last frozen; that the impurities are least if distilled water is used: that the number of bacteria in artificial ice is insignificant, under the prevailing methods of manufacture; and that the amount of zinc found in ice is insufficient to cause injury from its use.

Injections of Brown-Séquard's Fluid in Cutaneous Trophoneuroses.—Monnet (quoted by Brocq, *Journ. of Cut. and Gen. Urin. Dis.*, September, 1893) has tried injections of testicular juice in a young girl of nervous temperament, affected with symmetrical leucodermia of the trunk and lower extremities. Three cubic centimetres were injected morning and evening for six weeks. The general condition improved and the discoloration became gradually less, and at the end of three months the disease had almost entirely disappeared. Monnet has tried the same method in other skin affections, including three cases of ichthyosis, fourteen of neurotic eczema, several of "trophoneurotic erythema," and several of bullous and vesicular eruptions in the subjects of hemiplegia and general paralysis. Monnet explains the effect of the remedy in cutaneous trophoneuroses by its action on the nervous system, which is the source of the trouble. He thinks that injections of cerebrine would be more effectual in these cases. Brocq, while carefully avoiding committing himself on the subject, "cannot deny that the ideas on which rest the attempts of Dr. Monnet are both logical and perfectly rational."

THE ETIOLOGY OF THE DISEASES PECULIAR TO WOMEN.[1]

BY T. GAILLARD THOMAS, M.D.,

NEW YORK.

MR. PRESIDENT AND GENTLEMEN, Members of the New York County Medical Association: I esteem it a privilege to meet you here to night, and I desire, before commencing the reading of the essay which I hold in my hand, to thank you very cordially for the kindly feeling which prompted the invitation which resulted in my coming before you.

Right well do I remember the stormy hour which, nine years ago, gave birth to your organization. At that time I was fully in sympathy with your action, and ever since; although I own to a culpable inactivity in reference to working with you, I have felt an interest in your determined struggle for existence and progress, and an admiration for your signal perseverance and fixedness of purpose. May the second decade of your existence find your society still abreast of the most useful and distinguished bodies in this, the medical metropolis of America.

I do not come before you with the offer of that which the Athenians of old so ardently craved, "some new thing;" but in more humble guise I tender you "old wine in new bottles." For I propose to-night to read you an essay dealing with the generalities of one of the most trite questions in gynecology; not going into exact and minute detail, but endeavoring to present you at a glance a sketch which may prove usefully suggestive; a picture which I would not be willing to rely upon in the instruction of a class of medical students, but one which will, I hope, prove of some use to those of maturer years and developed experience. Borrowing an illustration from the painter's art, I should say that it is not preraphaelite, but impressionist, in its style. Its title is, "The Etiology of the Diseases Peculiar to Women."

Although morbid conditions may develop in connection with the genital system of the woman at any time of her existence intervening between "the cradle and the grave," it is beyond question true that there are in her life four great climacteric periods, in connection with which the great bulk of the diseased states to which she is liable develop; in which I should venture, at a rough estimate, to assume that nearly eight-tenths of all these conditions take their rise. These climacterics may thus be presented at a glance:

1st. Puberty, marked by progressive metamorphosis of the ovaries and resulting ovulation and menstruation.

2d. Marriage.

3d. Child-bearing.

4th. The menopause, or change of life, marked by retrograde metamorphosis of the ovaries and resulting cessation of ovulation and menstruation.

First Climacteric.—It is the ovaries which mark, by their rise to and fall from power, the beginning and the end of woman's functional career. Hippocrates, over two thousand years ago, enunciated the dictum, *propter uterum mulier est.* It was left for our own Peaslee to correct him by changing his formula to *propter ovaria mulier est*, which is the motto which he places at the opening page of his work upon ovarian diseases.

[1] Read before the New York County Medical Association, December 18, 1893.

True it is that with ovarian advance and retrogression a simultaneous change occurs in the uterus, but no one will to-day dispute the fact that the first constitutes the cause and the second the result; that the change in the first is the phenomenon and that in the second the epiphenomenon.

From the birth of a female child to its thirteenth year the girl is being prepared by nature for meeting the first great climacteric of her life; and fortunate is it for her if surrounding circumstances do not interfere with her development, or the ignorance or neglect of her guardians defeat the accomplishment of the result. During the first two thirds of this time of preparation the uterus, ovaries, and adnexæ of the child remain almost entirely dormant. Then, as she advances to the third period, they begin to undergo development, and toward the end of this period this development becomes accentuated, rapid, vigorous, and perfect. Then the ovules break away from the Graaffian follicles, the Fallopian tubes seize them, and pass them onward to the engorged and swollen uterus, and the great issue which translates the child from girlhood to womanhood has been met.

If the changes preparatory to this event have been properly performed, all goes well; but if from any cause the growing uterus has been checked in its development; been made misshapen so as to resemble a gourd, or been developed fully for half its bulk and made atrophic in the other half; or if the ovaries at the time of call to duty are wholly or in part undeveloped and incapable of performing their functions; or if the Fallopian tubes or vagina are constricted or impervious, a variety of so-called diseases show themselves, all of which are difficult of cure, and many of which are entirely incurable. If malformed ovaries exist the most agonizing ovarian dysmenorrhœa, amenorrhœa, or emansio mensium, with their sometimes coexisting hysteria, hystero-epilepsy, and even epilepsy, show themselves and hold out to the poor woman the prospect of a life of invalidism, or at least a lengthy and discouraging course of treatment. Who in this room does not recall many cases of this kind, which beginning with the very inception of menstrual life, have proved most rebellious to curative treatment? If the Fallopian tubes have been strictured by want of development, atrophy, or constriction by out-lying lymph, the girl suffers from severe pain at menstruation, or later in life becomes an invalid on account of sterility or tubal pregnancy. If the vagina is constricted or impervious, retention of blood in it or in the uterus becomes an important factor for evil.

Suddenly, the occurrence of this climacteric, created solely by ovarian dictation, makes an imperious call upon organs hitherto insignificant, and finding them unequal to the demand, a long list of ailments develop themselves as a consequence. On the first day of a month, the girl has been remarked upon as a type of female health, vigor, and beauty; on the fifteenth of that same month, the imperfect way in which she has grappled with the functions of her first climacteric have assured her physician that years of invalidism in all probability lie before her.

By the patient's friends, even by her physician, if he be a short-sighted and superficial observer, the trouble which has occurred is attributed to cold, to fatigue, to mental anxiety, or the like; but "the inexorable logic of events" is destined to belie this hope. If the chief symptom be dysmenorrhœa, the condition is carefully classified into "neuralgic, ovarian, congestive, or ob-

structive," and the physician very properly strives to overcome it by using his best efforts to meet a disability, which is commonly due to imperfect performance of those changes which mark the period styled "puberty." If the vagina be constricted or the cervical canal be impervious, they are distended and kept open; if the ovaries are at fault, general treatment by nerve and blood tonics, exercise and calisthenics, and local treatment by pelvic massage, and electricity and galvanism, are appealed to, and after a variety of means have been tried in vain, and grave symptoms still exist, the process of ovulation is abolished, and the evils dependent upon it relieved by the humane, scientific, and entirely defensible operation of removal of the tubes and ovaries.

Fortunate is it that many evils entailed upon the woman by "puberty" are oftentimes susceptible of complete relief. There are, however, some which project their influence into her future life and show themselves after marriage in various ways. For example, a deformed uterus may be the cause of frequent abortions, which no resource of art is capable of preventing; constricted tubes may give rise to hæmato-salpinx and perimetritis the outcome of peri-salpingitis; while obstruction to the transit of the fructified ovum into the uterus commonly gives rise to ectopic gestation.

Surely it is no exaggeration to style this one of woman's great climacterics, one of the periods in her existence which is fraught with the profoundest import for her health, her usefulness, and her happiness. If it be true, as I have said, that the period intervening between a girl's birth and her passage into womanhood is the time of preparation for this, her first great climacteric or critical period, much as to her fitness for meeting the issue will depend upon the proper physical development accomplished in this preparatory time, and all those who watch her career — physician, mother, and teacher — should join hands in sending her into the arena as thoroughly prepared as it is possible to make her for her new functions.

Second Climacteric. — The first climacteric being passed, the girl emerges from it a young woman, and enters into that period of her life which intervenes between puberty and marriage—speaking approximately, a period extending from the thirteenth to the twentieth year, covering about seven years of her existence. Although during this time falls, muscular efforts, exposure to cold, and pathological changes of tissue may, of course, produce disease, this is, to one who has successfully met the issue of puberty, usually a cycle of health and happiness. Then occurs a second climacteric, which sometimes proves a most baneful one to the healthy and robust woman who enters into it—marriage.

There are three morbid states which now frequently show themselves: First, the development of vaginismus, or spasm at the vaginal outlet; second, specific vaginitis, endometritis, and salpingitis; and third, the manifold evils resulting from the induction of abortion by women who resort to this fatal and criminal practice, not to protect their characters from disgrace, but merely to suit their social convenience, or from dread of the dangers of childbearing.

Of the first and third of these I shall say no more, as the management of the first is quite simple and generally understood: and as a mere mention of the third is all that I deem necessary. Of the second, I shall speak more fully and venture to quote upon it from an address given by me which has already appeared in print.

Until the last twenty years specific urethritis was regarded, in the male, as an affection of the most trivial import, as rapidly passing off, leaving few serious sequelæ, and offering itself as an excellent subject for jest and good-natured badinage. About two decades ago Dr. Emil Noeggerath published a dissertation upon this affection, which will forever preserve his name in the list of those who have accomplished good for mankind, and give him claim to the title of benefactor of his race. This observer declared, 1, that out of growing young men a very large proportion prior to marriage have specific urethritis; 2, that this affection very generally causes urethral stricture, behind which a "latent" or low grade urethritis is for many years prolonged; 3, that, even as late as a decade after the original disease has apparently passed away, the man may transmit it to a wife whom he takes to himself at that time; and 4, that the disorder affects, under these circumstances, the ostium vaginæ and urethra, and thence passes up the vagina into the uterus, through the Fallopian tubes, where it creates specific catarrh, and by this disease produces oöphoritis and peritonitis, which become chronic, and often end in invalidism and sometimes even in death. For this essay Dr. Noeggerath was assailed by ridicule and by contradiction. The matter has now been weighed in the balance and admitted to its place among the valuable facts of medicine.

Let me tell you my estimate of specific urethritis as a factor in the diseases of women, and let me assure you that I take no peculiar or exaggerated views concerning the matter. What I say will be vouched for by all progressive practitioners of gynecology to-day. Specific vaginitis, transmitted to virtuous women by men who are utterly ignorant of the fact that the sins of their youthful days are at this late period bringing them to judgment, is one of the most frequent, most active, and most direful of all the causes of serious pelvic trouble in women—one which meets the gynecologist at every turn, and one which commonly proves incurable except by the dangerous procedure of cœliotomy.

Think for a moment of the terrible position in which a high-minded, upright, and pure man finds himself placed without any very grave or unpardonable fault on his part. At the age of nineteen or twenty, while at college, excited by stimulants, urged on by the example of gay companions, and brought under the influence of that fatal trio lauded by the German poet—"Wein, Weib, und Gesang"—the poor lad unthinkingly crosses the Rubicon of virtue! That is all! On the morrow he may put up the prayer, "Oh, give me back yesterday!" But yesterday, with its deeds and its history, is as far beyond our reach as a century ago, and returns at no man's prayer!

Four or five years afterward this youth goes to the marriage-bed, suffering, unknowingly, from a low grade of very slight latent urethritis, the sorrowful memento of that fatal night, which has existed behind an old stricture, and a result is effected for the avoidance of which he would most gladly have given all his earthly possessions.

All this sounds like poetry, not prose; like romance, not cold reality. But there is not a physician in this room who does not know, and who will not at once admit, that every word that I have uttered is beyond all question true, and even free from exaggeration.

I mentioned, in speaking of the grave duties demanded by puberty, that one of the important functions of the physician in regard to the development of the girl during the thirteen years which precede it, is to instruct her and her guardians how to prepare her for the approaching issue. In language no less strong I would here insist upon the physician's duty to instruct men in all stations of life as to the importance of a "clean bill of health" in reference to gonorrhœa, both acute and chronic, before the marriage contract be entered upon.

Until a very late period the plan universally followed has been this: The man about to be married went to his physician, told him the history of a gonorrhœa, and asked if, now that all discharge appeared to have ceased, any danger would attend his consummating the tie. The physician would ask a few questions, examine the virile organ carefully as to discharge, and if the "outside of the platter" appeared clean, gave his consent to the union. The evil which has resulted from this superficial and perfunctory course has been as great as it has been wide-spread. To day the question of stricture, a slight, scarcely perceptible "latent gonorrhœa," with its char-

acteristic "gonococcus," is looked into, and not until all trace of disease is eradicated is permission given for the union. A marital quarantine is as necessary to-day in social life as a national quarantine is for contagious diseases in general.

Few men, however eager for matrimony they may be, would run the great risks attendant upon precipitancy if they only knew of them clearly and positively. In no field of medicine is the old adage, "Prevention is better than cure," more important than in this one. If physicians would do their duty fully in this matter, how many unfortunate women now languishing from "pyo-salpinx" would in the next generation be saved!

Third Climacterie.—Let us suppose that the girl has passed through puberty and become a wife, and that no evil has thus far befallen her in either of these stadia of her course through life. The probabilities are that within a year or two she will be called upon to face still another climacteric—that of utero gestation and childbearing.

The passage of the human fœtus through the short, mucous-lined canal which leads from the superior through the inferior strait of the pelvis is attended, even in labors apparently normal, by certain traumatisms which have a most disproportionate bearing upon the health of the woman who suffers from them. The reasons for this are not far to seek. Slit the cervix uteri or the perineum freely with a bistoury in a non-pregnant woman, and little, if any, serious injury would result. The parts would cicatrize and nature would prove herself abundantly able to deal with the trouble. But let a laceration of these parts be effected by the child's presenting part during labor, and a series of events takes place which casts its baleful shadow over the future life of the woman. This unquestionable fact is due to two circumstances which render the parturient woman peculiarly vulnerable to traumatism exerted upon the genital tract in any part of its extent. These circumstances are the following: 1. From the moment of fixation of the ovum upon the uterine wall until the end of gestation a rapid hypertrophy of all the sexual organs occurs. The only phenomenon in the physiology of the pregnant woman which is as wonderful as this is that retrograde process of involution which restores these parts to their normal state, so that at the end of eight weeks the immense uterus, the voluminous broad ligaments, the copious vagina, and the distensible perineum return to their lessened state of non-puerperality. 2. Wounds made in the genital tract of a non-puerperal woman are bathed during their repair by a bland mucus which is secreted by the glands of the cervical canal and by the vaginal membrane. Similar injuries inflicted upon the parts of a parturient woman are bathed by the lochial discharge, made up of ichorous material, holding in admixture flaking decidua vera, disintegrating placenta, and decomposing blood, which, even under favorable circumstances, sets up a sapræmia, and, under unfavorable ones, tends to the development of a dangerous septicæmia.

Such wounds are not prone to heal by nature's efforts, often assume bad features, and interfere greatly with that wonderful and subtle process of involution just alluded to. As a consequence an arrest of retrograde metamorphosis often affects vagina, uterus, uterine endometrium, and broad ligaments, and creates a marked disproportion in the normal relations of all the pelvic viscera at the same time that it weakens those supports which formerly sustained them. In this way we often see as direct and remote consequences of laceration of perineum and cervix uteri some or all of this long list of pathological results:

1. The vagina suffering from subinvolution and unsupported by the perineum, begins to undergo prolapse, its posterior and then its anterior wall pressing downward into the vulva.

2. Prolapse of one wall soon deflects a wall of the rectum and that of the other of the bladder, and misdirection of the forces of these viscera add their influence to increasing vaginal prolapse.

3. Traction by vagina, rectum, and bladder soon affect the uterus, and descent of this organ begins to show itself.

4. The uterus is the more prone to descend under traction because involution has been rendered imperfect in it, and its increase of weight and feeble support from subinvoluted broad and round ligaments render it helpless.

5. Menstruation now occurs, and a granular, almost fungoid, condition of the endometrium, existing in consequence of impaired involution, menorrhagia supervenes and adds its depreciating influence to the concatenation of morbid influences which are rendering the condition of the poor woman more and more wretched.

Could such a collection of untoward symptoms be possible from wounds inflicted by bistoury or scissors upon the perineum and cervix of a non-parturient woman? Not at all. Such results can be accounted for only by the interference of these traumatisms with the performance of an important physiological function, upon the fulfilment of which depends a return of every puerperal woman to the domain of health.

To sum up this part of my subject, there can be no doubt of the fact that a large proportion of the diseases peculiar to women are due to injuries inflicted upon the genital tract during labor, and that among them may be numbered, subinvolution of uterus, vagina, and perineum; fungoid endometritis; uterine catarrh; menorrhagia and metrorrhagia; any of the displacements of the uterus; prolapse of bladder, rectum, and vagina; cystitis; and secondary derangement of the blood and the nervous system, which react upon all the organs of the body.

To overcome these pathological results the obstetrician to-day repairs lacerations of cervix and perineum, lessens the volume of uterus and vagina, shortens the round ligaments, and scrapes away the entire lining membrane of the womb. When it becomes the accepted and universal practice to examine for these traumatisms after every labor, and to cure them by surgical means as soon as practicable after delivery, the diminution which will occur in the annual crop of sick women will wonderfully diminish.

Some years ago a writer upon this subject in an American periodical ventured to hint that avarice on the part of medical men greatly increased the sum total of gynecological operations. I am convinced that he was in error. A desire to multiply the gynecological work of the world ought to prompt an avoidance of the only means of cure possible in such cases as those of which I speak, and dictate the policy of leaving them to the baleful influences which have been mentioned. But the policy of the profession of medicine, which dates back through the ages as one always pledged to honest striving after the real good of society, needs no vindication at any man's hands to-day!

Some years ago, in my clinic in the College of Physicians and Surgeons of this city, being desirous of impressing the facts which engage our attention to night upon the students, I requested them to notice how frequently each patient who appeared before them would refer the cause of her disease to one of the critical periods mentioned, and agreed that we would review the subject at the end of a month. The result served to fix the fact most clearly in their minds by the frequent, indeed almost constant, recurrence of the phrases, "I was well until my periods began;" or, "My disease showed itself soon after marriage;" or, "I have never been in good health since my last labor, or since a miscarriage at such a time." That there were exceptions to this I need not mention, but they only appeared to be sufficiently frequent to prove the rule.

Fourth Climacterie.—We come now to the consideration of the menopause, or change of life, which has been from time immemorial known as the technical "climacteric" of woman.

When the far-reaching nervous influences exerted by

ovulation and menstruation upon the system of the woman, which continue active for thirty five years of her existence, are borne in mind, one is prepared to expect decided mental and physical manifestations when a sudden cessation of ovular activity occurs about the fiftieth year. And certainly at that time the nervous system of the woman does become especially liable to loss of balance, as demonstrated by hysterical and nervous manifestations, and even by a tendency to melancholia and other psychic derangements, while disorders of the menstrual flow become marked, decided, and troublesome, and serious tissue-changes in the pelvic viscera appear to be especially frequent. While all this is admitted it cannot be denied that too great stress has been laid upon this period of woman's life as a critical epoch, and that many pathological conditions occurring about this time have been credited to it which have had no connection with it at all.

The swing of the mental pendulum in reference to the matter must be carefully supervised as to both its extremes; the gynecologist being careful, on the one hand, to avoid an over-estimate of the importance of this epoch which leads to making it a shield for incapacity or ignorance; and on the other, being wary of an under-estimate, which may cause him to lose the great advantages which may result from a postponement of operative interference until its occurrence be allowed to exert its legitimate beneficial influence. Indeed I feel that I stand upon defensible ground when I assert that the chief significance of the menopause to the gynecologist exists in the fact that it constitutes a haven of rest for the woman from many ailments which are due to menstrual disorders and to hypertrophy and hyperplasia of the uterus. It ordinarily puts an end to subinvolution and uterine hyperplasia, to menstrual irregularities, to metrorrhagia, and to uterine myomata. With such certainty can these results be counted upon that operations for such conditions may be held in reserve, in the hope that by this climacteric the necessity for them may be avoided.

Some years ago, when the effects of galvanism in the cure of uterine myomata was upon the crest of the gynecological wave, a former pupil of mine, a man of great industry, enthusiasm, and honesty, requested me to read, prior to publication, a report of twelve or fourteen cases of uterine myoma in which small tumors had been completely cured, and large ones greatly benefited and checked in growth, by this, then new, therapeutic resource. It was not a report of his experience with the method, but one embodying his successful cases. Upon a careful analysis I found that all the cases of recovery and amelioration had occurred in women between forty-three and fifty three years of age, and that each recovery was coincident with cessation of menstrual flow and other signs of the menopause. The pleasure of reading this honest and laborious account of faithful work was never enjoyed except by the writer and myself, for it did not appear in print!

At the time of the menopause, as atrophy of the cervix uteri and atresia of the cervical canal take place, retention of discharges from the endometrium sometimes occurs, constituting hydro metra, hæmato-metra, or pyometra, and when decomposition of the arrested fluids supervenes, the rare condition of physo metra shows itself.

Two forms of senile vaginitis are apt also to develop themselves about this time—adhesive vaginitis, which closes the vaginal canal entirely, and hæmorrhagic vaginitis, which I have on several occasions seen mistaken for carcinoma uteri, on account of its causing sanguineous flow in a woman who has for some time ceased menstruating. In this connection this diseased state is of importance, for the patient will always come to the physician in the greatest state of alarm. Fortunate is it that this alarm may be quieted by the promise of complete recovery.

Lastly, at this climacteric procidentia of the atrophic senile uterus is apt to occur from rapid absorption of adipose tissue in the pelvis, which causes it to descend from want of support, and inflicts upon the woman a disability at the end of her career, and after she has borne triumphantly the burdens of life.

This completes the list of the most important of the pathological conditions which develop in connection with the menopause, the fourth climacteric of woman's life, and constitutes all that I have to say upon this subject this evening.

OPERATIVE SURGERY OF THE GALL TRACTS, WITH ORIGINAL REPORT OF SEVENTEEN SUCCESSFUL CHOLECYSTENTEROSTOMIES BY MEANS OF THE ANASTOMOSIS BUTTON.

By JOHN B. MURPHY, M.D.,

CHICAGO, ILL.

PROFESSOR OF SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS; PROFESSOR OF SURGERY, POST-GRADUATE SCHOOL AND HOSPITAL; ATTENDING SURGEON, COOK COUNTY HOSPITAL; ATTENDING SURGEON, ALEXIAN BROTHERS' HOSPITAL; CONSULTING SURGEON TO HOSPITAL FOR DESTITUTE CRIPPLED CHILDREN; VICE-PRESIDENT OF NATIONAL ASSOCIATION OF RAILWAY SURGEONS, ETC.

(Continued from page 42.)

8. *Cholecystectomy.—Total Extirpation of the Gall-bladder.*—This operation was introduced by Dr. Langenbuch. At first there was most bitter opposition to the operation, but it has now obtained great recognition. For a certain class of cases it is the operation *par excellence*, 1, on account of its safety; 2, because it completely fulfils the indications. Langenbuch is sustained in the theory of his operations by the fact already mentioned, namely, absence of the gall-bladder being harmless as far as the health of the patient is concerned, as demonstrated by the large number of animals and men in which this viscus has been found to be congenitally absent, and made no apparent difference in their health. I have found in dogs, on which I have performed this operation, that their health was not interfered with in the slightest.

The only question of gravity for the consideration of the surgeon, as long as its absence does not materially affect the patient, is, What are the dangers of the operative procedure itself? That these dangers are not great is shown by the following statistics. We have collected in all 65 cases; of these there were 11 deaths, a mortality of seventeen per cent, which is even more favorable than cholecystostomy; and this operation is rapidly finding favor with surgeons, notwithstanding the assertions of Tait, when the operation was first suggested in May, 1884, that it was absurd; in June, 1885, that it was "radically absurd;" and in October, 1889, that it was "intrinsically absurd" (Courvoisier), another illustration of how valueless a man's opinion may be of an operation that he has not tried. The indications for this operation are, 1, hydrops and empyema of the gall bladder, when it is already disconnected from the choledochus by occlusion of the ductus cysticus; 2, in severe chronic recurrent cholelithiasis vesicularis; 3, in severe diseases of the wall of the gall bladder itself, ulceration, gangrene, contraction, and carcinoma; 4, in internal rupture or wounding of the gall bladder, when suture is difficult or impossible. It is contra indicated by strong adhesions to its surroundings, by broad and close attachments to the liver, in all permanent closures of the choledochus.

9. *Choledocho-lithotripsy, or Crushing of Gall-stone in the Choledochus.*—The operation has been performed three times with success, by Credé, Courvoisier, and Kocher. It was found in these cases that there were fragments after the crushing that would not pass through the choledochus, but might regurgitate back into the gall bladder. There is also no certainty that the remainder of the canal is patulous below the point where the fragments lodged. Credé's patient had severe attacks of colic and fever in passing the fragments. Again, there is danger, in the act of crushing the stones, of injuring the walls of the duct so as to subsequently cause a perforation; for these reasons this operation should not be performed.

10. *Choledocho-lithectomy, with Subsequent Suture of Duct.*—This operation has been performed five times,

with two deaths, giving a mortality of forty per cent. It is a very difficult operation to perform, as the duct is deeply situated and the escape of bile in the field of operation after the incision is very annoying to the operator. This operation was first performed by Courvoisier, and he deserves great credit for his ingenuity and courage in devising and undertaking it, as well as being the first to perform a successful cholecystendysis, and to do the first successful choledocho lithotripsy. This is to be undertaken—1, where the stone is large and firmly impacted in the duct, and when the patient has symptoms of intermittent fever and chills; 2, where the stone is impacted in the duct and the ductus cysticus is obliterated, preventing the formation of a gall-bladder and intestinal fistula for the escape of bile; 3, where it has produced ulcerative perforation and the wall at the opening is in a healthy condition, otherwise the gall-duct should be excised at that point, both ends ligated, and a cholecystenterostomy performed.

Case I. *Choledocho-lithectomy.*—Mrs. Mathilda B——, aged thirty-five, multipara; admitted to hospital September 20, 1893. Enjoyed perfect health until three years ago; at that time had first attack of colic; intense pain of sudden origin in right hypochondriac region, very sensitive under right costal cartilage; pain continued several hours, followed by vomiting; was not followed by jaundice. Two years later similar attack, with no jaundice. Five weeks ago had third attack. Has had frequent severe attacks of pain since the beginning of the last one a week ago, which have continued to the present time (October 20, 1893). The symptom of jaundice made its appearance for the first time four weeks before admission, and is still present. She does not know that she ever passed a gall-stone. Never had any urinary difficulty. Stomach always good. Was never free from tenderness in right epigastric region since time of first attack.

Present Condition.—Very icteric. Rapid, feeble pulse, expression of severe suffering, complains of great thirst, anorexia. Very sensitive in right hypochondriac region. No tumor perceptible. Temperature, 103° F.; pulse, 138; respiration, 34.

Diagnosis.—Hepatic calculus impacted in ductus choledochus.

October 21st, 8 A.M. Pulse, 100; temperature, 102.8° F.; respiration, 36. P.M., pulse, 102; temperature, 103° F.; respiration, 36.

October 22d, A.M., ——. P.M., pulse, 96; temperature, 102° F.; respiration, 40.

October 23d, A.M.—Pulse, 94; temperature, 99° F.; respiration, 30.

Operation.—October 23d, 11 A.M. Dr. Murphy, assisted by Drs. Hartmann, Wittwer, and Cortebein, performed laparotomy; found gall-bladder contracted to a tube, large calculus, one-half inch in diameter, situated in the middle of the choledochus. Gall-bladder could not be utilized for approximation to the intestine. It was decided to remove the calculus from the common duct, which was thoroughly exposed. An incision one-half inch long was made in the duct, parallel with it, stone extracted. The opening in duct was united with continuous suture. Gauze drainage. Time, 45 minutes. There was but very little hemorrhage during operation, and none whatever after the suturing. Some shock. Pulse, 11.40 A.M., immediately after operation, 64; respiration, 30. 5.30 P.M., pulse, 72; temperature, 97° F.; respiration, 32. 10 P.M., pulse, 78; temperature, 97.4° F.; respiration, 32.

October 24th, 8 A.M.—Pulse, 94; temperature, 98.8° F.; respiration, 32. Rested well during night; nauseated, but no vomiting since operation.

October 24th, 6 P.M.—Pulse, 144; temperature, 103° F.; respiration, 36.

October 24th, 12 P.M.—Pulse, 108; temperature, 101° F.; respiration, 26. Condition much improved; pulse still feeble.

October 25th, 2 A.M.—Pulse, 110; temperature, 102° F.; respiration, 35. Pulse very weak. Died at 3 A.M., very suddenly.

Autopsy was not allowed. It is therefore impossible to say what was the cause of death.

You will find, in reviewing the results of these operations, that the mortality is greatest in the operation of cholecystenterostomy, in one sitting, by means of suture, in which thirty-five per cent. of the cases terminated fatally. Next high in the scale of mortality is cholecystostomy of one sitting, the operation which is most prevalent and performed more frequently than any other, and almost as frequently as all the others combined; its mortality is nineteen per cent. This great mortality should cause every thoughtful operator to endeavor to find some other means whereby his patients will not be jeopardized to such a great degree; and while the mortality is nineteen per cent., the percentage of perfect recoveries is only about fifty-one per cent., making the chances for life in the ratio of five to one, and the chances for complete recovery but one to two. The next operation in fatality is cholecystendysis, with a mortality of twenty-three per cent., very little more than cholecystostomy. Then comes cholecystectomy, with a mortality of seventeen per cent. The most favorable of the older operations is cholecystostomy, in two sittings, in which we have a mortality of ten per cent. Lastly, consider the operation of cholecystenterostomy by means of suture; from all cases I have been able to collect the mortality is thirty five per cent.; with this contrast the cases of cholecystenterostomy for gall-stones by means of the anastomosis button, with one hundred per cent. of recoveries. The author's method needs no further laudation than that shown by a comparison of the percentages. This favorable showing was not produced by one operator or by myself, but by nine different operators, and in one case, that of Dr. Mayo, on a patient seventy-one years of age.

The classes of cases requiring surgical interference in lesions of the gall tracts are as follows:

1. In all cases of obstructive jaundice, where the jaundice exists during a period of two weeks.
2. In all recurrent cases of obstructive jaundice.
3. In cases of recurrent cholecystitis.
4. In recurrent cases of colic from cystic duct obstruction, always without jaundice.
5. In retention cysts of gall-bladder.
6. In malignant growths of gall-bladder.

The early operation is by all means the most favorable, as the gall bladder is not contracted and is free from adhesions.

In reference to the criticisms by Professor Senn,[1] I would say that while he does not comment on the use of the button in cholecystenterostomy, some of his criticisms would be applicable to the use of the button in that operation, as well as operations on the intestines; therefore I deem it proper to treat them in this article. *First*, he says that "it is no improvement on the rings employed by Denan more than half a century ago." The correctness of this statement can be readily tested by a cursory comparison of the two devices, cuts of which are herewith submitted (see Fig. 9). *Second*, he says that "a foreign body is left in the intestinal canal which may become a source of danger on its way to the distal end of the alimentary canal." Will it become a source of danger, and when? The ileo-cæcal valve is the place in the normal intestinal tract in which it would be most likely, if at all, to produce an obstruction. That this valve in its normal condition allows the passage of bodies much larger in diameter than the button, is shown by the many experiments on that portion of the canal.

It is further shown by the clinical observation of medical practitioners, who from time immemorial have seen children swallow coins, nuts, peach-stones, marbles, and other foreign bodies, much larger in proportion to the child's intestine than the button recommended, and pass them without producing unpleasant symptoms.

[1] Journal of the American Medical Association, August 12, 1893.

This is considered by doctors to be of so little danger that they advise the patient "to pay no attention to it, and forget that such a thing occurred." What surgeon would become hysterical if the child of one of his patients swallowed a coin or marble? Admit that a coin or marble, under certain pathological conditions, has produced trouble; to the one such case there are thousands that have not. So it will be admitted that with cicatricial contraction of the bowel or a malformation of the ileo cæcal valve, obstruction might be produced by the button; but the proportion of these cases would be about the same as the proportion of cases of trouble produced by the coin or marble, and so small as to be scarcely worth serious attention. It could with equal force be argued that child-bearing should be discouraged because occasionally there is difficult or impossible delivery of a child on account of pelvic deformity or other causes.

I have now reports of three hundred operations and experiments with the button. The obstructions so much dwelt upon by the critics of the button did not occur in one of my cases, nor has it "come to my knowledge" that it occurred even once in the cases of others who have performed the operation.

Dr. W. W. Keen, in the same paper from which Senn

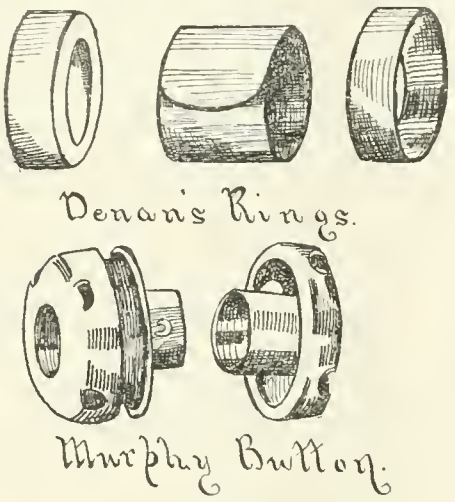

Fig. 9.

quotes a portion of a sentence referring specifically to the objection, says, "On the whole, however, I do not feel that this objection is a very serious one, since the condition requiring the use of the buttons, if they be used, is one which must dominate all other risks." [1]

It can therefore be seen that the danger of obstruction by the button is so slight that it is entitled to no weight in view of the ease with which it is inserted, and the certainty with which it fulfils its purposes.

Third. "Any instrument, suture, or ligature used in effecting the continuity of a wounded or divided bowel that produces gangrene, must be looked upon as a source of danger." The term gangrene is misleading in this connection; the term the doctor intended to use, no doubt, was pressure atrophy. Every suture, every mechanical means that is used, every ligature that is tied in approximating the intestine, produces pressure atrophy in a greater or lesser degree, or it gives no support. Shall we discard all these useful measures together? Pressure atrophy (gangrene, Senn) in vascular tissues is limited to the area of pressure in which the circulation is shut off and is always controlled thereby.

The button above all others—suture, rubber-rings, bone-plates, etc.—protects the peritoneal cavity. There is no suture on the peritoneal surface; there is nothing left within the peritoneal cavity; it is shut out and sealed up by a uniform compress. This compress closes as pressure atrophy takes place, and closes in the direction of pressing the surfaces desired to be agglutinated, closer and closer together. This is not accomplished by any other device. True, there is a substance in the calibre of the intestine, call it foreign if you please; so are the materials used as food to some degree foreign materials, but they, like the button, are on the safe side of the intestine, within it, not without.

Fourth. "Because the lumen of the connecting part is not large enough as a temporary outlet for the intestinal contents above the seat of operation." This objection is not tenable. The surgeon well informed on the physiology of the small intestine knows that its contents are always fluid, except in cases where some indigestible solid substance is introduced. Patients are not usually allowed an ostrich diet for a few days following an intestinal anastomosis. No matter what medicine may be given, it does not render the contents of the small intestine solid; they are always fluid. The amount of fluid that would pass through the central opening in a medium-sized button in twenty-four hours can be easily computed, and represents several times the weight of the entire body, while the average amount of fæces in the same time is five ounces.

Fifth. The fragment of a sentence quoted by Senn from Keen's article is such an inadequate representation of the scientific and fair manner in which this recognized authority treats the subject, that I venture to quote more extensively from Keen's article as follows (pp. 660 and 661): "The speed and certainty with which an anastomosis can be made once the bowel is prepared for it, are certainly advantages which the button possesses over all other means of anastomosis, whether by simple suturing or by bone-plates, catgut, or other rings." "It is certainly a most happy mechanical invention, especially the method of fastening it by what is practically a secure screw, and yet instead of being rotated in order to fasten it, it simply needs to be pushed home. The two projecting teeth which answer the purpose of the male screw, make it one of the most ingenious devices I have ever seen." From Dr. Keen's postscript I will quote the following, first, as showing the perfection of the union: "From the outside one would almost think that it was the normal termination of the ileum in the colon; no more perfect union could be imagined." In regard to the contraction found by Dr. Keen at the autopsy which he reports, we are compelled to admit the force of the suggestion made to me by Dr. W. J. Mayo, that a vital point in the report of that autopsy is omitted, namely, a comparison of the diameter of the ileum before operation and at the autopsy. Before operation there was undoubtedly, with a chronic obstruction, distention of the ileum. Did the opening contract more in proportion than the ileum itself, and was not the contraction of the opening due to the contraction of the ileum from its expanded, obstructed, pre-operative condition, to its normal, contracted, empty condition produced by a free escape at the anastomosis as found at the autopsy? An analogous contraction to this is shown in cases in which a cholecystenterostomy is performed experimentally. The opening which originally was the size of the button used is reduced, not by the contraction of the cicatrix, but by the contraction of the gall-bladder, which, after a number of weeks, is reduced to the size of a cystic duct. Dr. C. E. Ruth,[1] of Keokuk, says: "I wish to call especial attention to the specimen in which an approximation was made between the duodenum and gall-bladder. You see that what was a gall-bladder has ceased to exist as such, and nothing remains of it but a duct. Its contraction has narrowed the opening which delivered a five-eighths inch button until it is the size of a slate pencil, and shows well-marked folds of mucous membrane at its margins that must act as a valve to prevent the passage of intestinal contents into the gall-bladder." A year and four months have elapsed since the first human case of cholecystenterostomy with the button, and in all of the other cases a shorter time has elapsed,

[1] Annals of Surgery, June, 1893, p. 660.

[1] The Omaha Clinic, September, 1893.

and the symptoms of obstructive jaundice have not appeared in any of them, as was feared by Dr. Abbé.

The following is a report by Dr. J. Henry Barbat, of San Francisco, of a case in which an autopsy was made.[1] The operation of gastro enterostomy was performed on December 26, 1892. The case was one of carcinoma involving a large portion of the pyloric end of the stomach. The button used was made from the description given in my paper.[2] The patient gained ten pounds in three weeks after the operation. She became so indifferent about her food that she ate beefsteak, potatoes, fish, fried tripe, bananas, and other food difficult of digestion. These were all eaten before the button was voided, and still there was no obstruction. She died February 10th, forty-six days after the operation, of an acute pulmonary infection. The following is the doctor's report of the autopsy:

"I examined the stomach and found the opening into the bowel large enough to almost admit two fingers, and the union absolutely perfect." You will note that the length of time that had elapsed between the time of operation and death was only one day less than in Keen's case, still the opening remained almost large enough to admit two fingers.

Dr. C. E. Ruth[3] comments as follows: "This not only simplifies, but gives an element of certainty in this formerly impracticable operation, that is scarcely believed until seen. Its importance can scarcely be overestimated. The operation has been done successfully on eight persons. You will notice that no such contraction occurred in any of the specimens as that which occurred between the gall-bladder and the duodenum; in fact, none whatever. I have done gastroduodenostomy, cholecystenterostomy, lateral and end-to-end approximations, specimens from all of which I now show you, and in no case did I fail to get firm union without a fistula or a particle of fecal or gaseous extravasation."

Dr. F. Andrews, of Chicago, says:[4] "It is the means *par excellence* for establishing a gastric or fecal fistula. By having a string attached, as soon as pressure atrophy has released the button it is at once drawn out of the wound, without being allowed to pass through the intestinal tract."

Dr. J. McFadden Gaston says, referring to the button:[5] "This device for uniting different structures has now been tested in a sufficient number of cases to afford a reasonable reliance upon its efficacy. The results were entirely satisfactory in the demonstration of the adaptation of the button for anastomosis, and there can remain but little doubt of a communication with surrounding adhesion being accomplished by it, with more expedition than by processes heretofore adopted."

Dr. Hugh Ferguson, of Winnipeg, used the button for a case of pylorectomy with end approximation of duodenum to side of stomach, also in a case of cholecystenterostomy; both successful. In a personal letter he writes as follows: "I am more than pleased with the anastomosis button. It is really more than an anastomosis button, and should be designated 'Murphy's Intestinal Button.' If a discussion on the button arises at the Pan-American Meeting, you may quote these two cases. The button cannot be too soon known."

Dr. W. B. Rogers, of Memphis, Tenn., July 30, 1893, writes: "I would say that immediately on my return here, I had an opportunity for using your button for the operation of cholecystenterostomy, and it worked like a charm."

Dr. R. Weir, of New York, writes: "I have used the button for cholecystenterostomy and like its ease of application, though the fatal ending prevented the fullest test being made. The result, however, was not due to the method, but to the case itself, which was neoplasm compressing the common duct and engaging both the liver and pancreas."

Dr. J. Henry Barbat,[1] who used the button in performing a gastro enterostomy, comments as follows: "An anastomosis may be done by this method with perfect safety, and with a result that cannot be obtained by any other method. The day of bone-plates, catgut-rings, and numerous other devices that have been used in performing the anastomosis operations, is past, and every surgeon should provide himself with a set of the buttons, which does not require an extensive amount of operative skill to use."

The contraction of the gall-bladder occurs in more than eighty per cent. of the cases of cholelithiasis. This contraction is the result of the cicatricial contraction produced in the gall-bladder by a chronic inflammation or irritation of it by the gall-stones; therefore the earlier the operation is performed, the less liable we are to find contraction. There is another danger, and that a serious one—perforation of the tracts by the calculus. I have been called in consultation, within the last eighteen months, in three cases of perforation of the gall tracts, all with infective peritonitis, and all died. The history of repeated attacks was given. In one case the patient had the question of operation under advisement on account of the frequency of attacks. None of them were suffering from colic or obstructive jaundice at the time of the perforation, which shows that there is danger even in the quiescent stage. Another reason for the early operation is the danger of malignant growth being produced by the constant irritation. I have seen a large number of autopsies on this class of cases. In looking over the records of the pathological institutes, they afford abundant proof of the statement that a considerable percentage of cases of cholelithiasis terminate with carcinoma of the gall tracts. These reasons, along with the dangers which accompany an acute attack of obstructive jaundice, are, I think, considering the small percentage of mortality, sufficient to justify early operative interference.

Report of Cases of Cholecystenterostomy.—CASE I. A. Q——, aged thirty five, female; admitted to the medical department of Cook County Hospital, May 27, 1892. Transferred to the surgical division of the hospital, June 10, 1892, and came under my care. Gave the following history: During the last fifteen years has had stomach troubles; pain and tenderness in the epigastrium; the attack would last from two to four days, was almost always accompanied by vomiting, not by jaundice. Had pain in back since childbirth; suffered from chronic constipation. One of these attacks was accompanied by jaundice for the first time December 14, 1891. At that time she had constant and intense pain for twelve hours, and an aching pain and tenderness in the epigastrium for two months following it. Jaundice cleared in about two months. During the past few months the attacks of stomach trouble would last from twelve to twenty-four hours. In February the present attack began, accompanied by jaundice and severe pruritus, which has been constant from that time up to date. These symptoms increased in severity up to the time she was admitted into the hospital. While in the medical department her jaundice was constant; her mental condition became very much impaired, and her emaciation rapidly increased.

Condition when Admitted to the Surgical Department.—The patient intensely jaundiced; very much emaciated; has a point of tenderness in the right hypochondriac region just below the margin of the rib; no tumor to be felt. The urine contains a large quantity of bile; no albumin. The patient suffers from considerable mental derangement; very slight elevation of temperature.

June 11th.—I decided to perform cholecystenterostomy, by means of anastomosis button, which I had used for the first time on a dog six days previous. An incision three inches long was made, three inches to the right of the median line, extending directly downward. The gall bladder was found distended, non-adherent, and contained a large number of small calculi. Two

[1] Pacific Medical Journal, April, 1893.

calculi were found in ductus choledochus and allowed to remain. Duodenum and gall-bladder were both drawn into the wound; an incision was made in the duodenum and half of the button inserted. A running thread was put in the gall bladder, an incision made, and the other half of the button inserted. The gall-stones were not removed. There was considerable escape of bile, as the gall bladder was not aspirated before putting in the button. The button was then pressed together without difficulty, and the mass dropped into the abdominal cavity. Time from the opening of the peritoneum until the closing of same, eleven minutes. After the operation the patient showed no unpleasant symptoms; temperature at no time exceeded 100° F., and in fourteen days from the operation she was allowed to walk about the ward. The jaundice rapidly disappeared, and three weeks after the operation there was no trace of bile in the urine. The patient was of a very hysterical temperament after her mental condition improved; she noticed that she was an object of observation, and became so erratic that we could not control her at the hospital and were compelled to discharge her five weeks after the operation. Up to that time she stated that she had "not passed the button." She was apparently well in every particular. The button used in this case was inferior to the improved one now used.

October 28, 1892.—Patient was examined by Dr. H. R. Wittwer. He found the jaundice had not returned; there was no bile in the urine, and the patient was in excellent health. He could not ascertain whether she had voided the button or not.

August 20, 1893.—This patient began to suffer from pain in the right side and temperature in December, 1892, and continued to January, 1893. She was in one of the hospitals in this city. An exploratory operation was made over the site of the former operation by the attending surgeon, a contracted gall-bladder was found firmly and perfectly united to the duodenum, but no button there. Subsequently the cause of the temperature was found to be an abscess of the lung, not an empyema, which was drained, and the temperature at once disappeared. At no time since the first operation has the patient been jaundiced, nor has there been bile in the urine.

The following case was referred to me by Dr. Hoelscher, who, with Drs. Wiener and Lee, assisted me in the operation.

Case II.—Mrs. B——, aged thirty-eight, widow, has three children. Parents still alive, aged seventy six and seventy-four, respectively. Brothers and sisters well; no history of any hereditary disease.

Dr. Hoelscher saw the patient for the first time October 7, 1892, and found her as follows: "Healthy, well-nourished appearance; pain of sudden onset in the epigastric region, and from this point it gradually extended over the whole abdomen. She had vomited the contents of the stomach and some bile on two occasions after the seizure with pain. Bowels were constipated and had been in this condition two or three days before the seizure. Vesical tenesmus and diminished quantity of urine. Gave no history of any previous pain, gastric disturbance, jaundice or colics." On examination found a tumor in right hypochondriac region, extending downward into the iliac region, and terminating in a rounded smooth end; could be distinctly felt in lumbar region, was movable and tender on pressure; there appeared to be a deep fissure between the tumor and the liver, no fluctuation apparent, bowel or colon not overlying the tumor. The diagnosis could not be determined, but it was presumed to be some lesion of the kidney, so it was decided to make an exploratory laparotomy.

October 19th.—I made an incision three inches long, from the edge of the tenth rib directly downward toward the border of the ilium. The tumor was exposed and found to be a very much enlarged gall-bladder, containing large calculi. The viscus was œdematous, red, and thickened. It was decided to make a cholecystenterostomy with the anastomosis button (No. 2). The gall-bladder was aspirated, and the running thread inserted. The running thread was then inserted into the duodenum and the intestine incised, and the male half of the button placed in position, the female half was then placed in the gall-bladder through a slit made between the running thread, and the button closed. The gall-bladder measured at least one centimetre in thickness and was very œdematous. There was no difficulty in inserting the button. The gall stones were allowed to remain, as I do not consider it necessary to remove them unless they are larger than the button. They will pass out after the button escapes.

October 20th.—Temperature, 101° F.; pulse, 96. Vomited considerably during the night and complained of headache, which seemed to be effects of anæsthetic. There was no pain nor abdominal tenderness.

October 21st.—At 5 P.M. yesterday the vomiting ceased, and the patient is feeling very well this morning.

October 27th.—The patient has had no unpleasant symptoms since October 20th. This morning (eight days after operation) in the stool were found two large gall-stones. The larger one weighed 117 grains (7.8 gm.); its longest diameter one inch, its shortest seven-eighths inch. The second stone, 102 grains (6.8 gm.); its longest diameter seven-eighths of an inch, its shortest three-fourths of an inch. It will be noticed that the shortest diameter of the larger stone measures exactly the same as the diameter of button used. The patient is feeling very well and is sitting up in bed. Complete primary union. Button passed eighteen days after operation.

August 20, 1893.—The patient has excellent health and not the least symptom of her previous trouble.

Case III. *Cholecystenterostomy with Button No. 1.*—This case was referred to me by Dr. J. H. Hoelscher, who gave me the following history: Mrs. Z——, aged thirty-six, married, six children. Enjoyed perfect health until twenty-two years of age; at that time, three months after childbirth, had an attack, of short duration, of severe epigastric pain and vomiting. It was not accompanied or followed by jaundice. Ever since that attack she has had digestive disturbances, as distress following certain kinds of food, eructations of gas, constipation, loss of appetite. Four years ago she had a similar attack of pain in the epigastrium, accompanied by vomiting. From that time on the pain returned every five or six weeks, up to five months ago, when she noticed a constant aching pain and tenderness in the right hypochondriac region, that persisted until the present time. The pain and soreness were very much increased after working in a stooping posture. She has suffered much from general debility, and complains of slight and frequent chills. Throughout the entire progress of her disease jaundice was never present. The urine was tested several times with negative results. She does not give a distinct history of having had hepatic colic.

About three months ago she found small particles, the size of mustard seeds, in the fæces, which someone told her were gall stones. There is no positive evidence that she ever passed a gall stone. Physical examination revealed heart and lungs normal; liver not increased in size. Manipulation reveals a pear-shaped, hard tumor in the region of the gall bladder, measuring about three inches in length and two in width. It moves synchronously with the diaphragm in respiration. On pressure considerable pain is produced and a slight creaking sensation is felt by the fingers. It can be separated from the kidney and can be moved considerably from side to side.

The diagnosis of gall-stone was made by Dr. Hoelscher, and the case was referred to me for operation.

Operation, November 23, 1892, assisted by Drs. Hoelscher and Lee, in the presence of Dr. Nicholas Senn, Dr. Dunne, of Minneapolis, and Dr. Mayo, of Rochester, Minn. The incision was made the same as in Case II.; contracted gall-bladder packed full of gall stones slipped into the wound. A little difficulty was experienced in drawing the duodenum forward, as some old adhesions existed. The running threads were inserted in gall bladder and

duodenum; male half of button placed in duodenum and held by an assistant. An incision was made in the gall-bladder, which was found so full of gall-stones that half of the button could not be inserted without removing some of them. A dozen were quickly picked out with the dissecting-forceps. About twice as many were allowed to remain. The female half of the button was inserted in the gall-bladder and the running thread tied. Button pressed together. Toilet of field of operation was made with dry sponges and the viscera dropped back into the abdomen. Deep and superficial row of sutures in abdominal wall. Time for entire operation, twenty-one minutes. The time for inserting the button was not taken. Patient rallied rapidly from the anæsthetic. Pulse after operation, 70; temperature, normal. Neither nausea nor vomiting.

November 25th.—Pulse, 78; temperature, 100.5° F. Patient complains of slight pain at seat of operation. No tympanites nor abdominal tenderness.

November 28th.—Patient expresses herself as feeling very well. At no time since the operation has patient's temperature exceeded 100.5° F. She is allowed to take a quantity of liquid nourishment, but not sufficient to satisfy the appetite. I consider her now out of danger. The ease and rapidity with which this operation was performed satisfied those who witnessed it, as well as myself, that the operation of cholecystenterostomy by this means is relieved of many of its dangers and all of its difficulties. Dr. Hoelscher is to be congratulated on his diagnosis in this case, in the absence of so many important symptoms.

August 20, 1893.—Dr. Hoelscher reports to me that this patient has enjoyed better health since the operation than she had for years previous. Not one of the symptoms returned.

Case IV.—Mrs. F——, referred to me by Dr. Hoelscher, who furnished the following history: Patient aged fifty six, married, has several children. For the last four years has suffered from attacks of difficult breathing and palpitation. These attacks were usually accompanied by pain and tenderness in the right hypochondriac region. On three or four occasions in the past year she has had colic, and most of that time was unable to work and confined to her room. These attacks were never followed by jaundice, and no vomiting. Never passed gall-stones.

December 11, 1892.—Patient had a severe attack of pain, with vomiting and great tenderness on pressure in the right hypochondriac region. This continued up to the time of the operation, but no jaundice was present and no bile in the urine. Dr. Hoelscher requested the operation of cholecystenterostomy.

December 18th.—Dr. Murphy, assisted by Drs. Hoelscher and Lee, performed cholecystenterostomy by means of the button. A number of gall-stones were removed. The button was easily inserted. The abdominal wound dressed. The patient was removed from the table in excellent condition. Her convalescence was uneventful.

August 20, 1893.—Patient called at office and reported that she has enjoyed better health since the operation than for years. Has not had a recurrence of the dyspnœa or palpitation. Has gained very much in weight and strength. No recurrence of pain.

Case V.—History and particulars furnished by Dr. E. W. Lee, in whose practice this case occurred. Mrs. L——, aged forty-eight, married. At intervals in the last three years patient has suffered from severe attacks of colic, accompanied by nausea and often vomiting. The pain was always located in the right hypochondriac region, and often in the "pit of the stomach." These attacks would last for several hours, and then would suddenly disappear, leaving a soreness at the seat of pain. They were never accompanied by jaundice until the present attack, which began February 14, 1893, six days before operation. This attack was more severe and prolonged than any of the previous ones. The vomiting was very severe. The tenderness over the gall-bladder was extreme. Operation, February 20, 1893. Dr. E. W. Lee, assisted by Drs. Murphy, Hartmann, and Wittwer, performed cholecystenterostomy by means of the button. The gall bladder was very much contracted, and there were many adhesions. The adhesions were separated, and a medium-sized button inserted, producing a perfect approximation. Several small stones were removed at the time of the operation. The recovery was uneventful. Patient passed the button March 6th, fourteen days after the operation. A number of small stones were passed subsequent to the operation.

August 26th.—Patient has been able to work more since the operation than for three years previous. Has had no colic or digestive disturbances.

Case VI.—Mich. D——, Alexian Brothers' Hospital. Transferred to my service by Dr. Hoelscher. Aged forty-two, male, single. Several weeks ago he began to have pain and a sense of pressure under the border of the right ribs. This was sometimes accompanied by severe pain, with nausea and vomiting, but no jaundice. One week ago the pain became very much more severe, and was soon followed by jaundice. Shortly after the jaundice appeared the pain ceased, but the tenderness remained over the region of the gall bladder.

Status præsens.—Icterus very marked, large quantities of bile in the urine, fæces acholic. Tongue dry and brown; temperature, 100.4° F.; pulse, 86, full and regular. The patient very tender over the lower margin of the right costal arch. An induration could be felt, but the gall-bladder could not be outlined.

Diagnosis.—Cholelithiasis with occlusion of choledochus. Operation, May 6th. The patient acted very badly under chloroform, so it took ten minutes to open the peritoneal cavity. The gall-bladder was aspirated and joined to the duodenum with the button in ten minutes, and ten minutes was consumed in making the toilet and suturing the wound, making thirty minutes in all. A small stone was removed from the gall bladder, but the obstruction in the common duct was not disturbed. The patient made an uneventful and rapid recovery. The jaundice rapidly disappeared after the operation. The patient was up and about the ward on the fifteenth day. Voided the button May 22d, sixteen days after the operation. The urine showed a negative reaction for bile, May 14th.

August 15, 1893.—The patient reported at the hospital. Has gained very much in weight and is enjoying excellent health. No return of his symptoms.

Case VII.—Mrs. D——. Called to see patient by Dr. T. J. Conley, who furnished me the following history: Patient, widow, aged fifty-four. Has had several attacks of pain in the right hypochondriac region for the past two years. Two weeks before the present attack suffered from a severe purulent bronchitis, and was much emaciated by it. Shortly after the bronchitis subsided she had an attack of pain and pressure in the right hypochondriac region. She never had an attack of jaundice. On examination, January 29, 1893, patient emaciated, suffering from bronchitis; pain and tenderness in the right hypochondriac region; a small tumor can be felt in the same region. It is movable and can be separated from the kidney.

On January 31st, Dr. Murphy, assisted by Drs. Conley, Lee, Hartmann, and Wittwer, performed cholecystenterostomy. There was no difficulty in inserting the button. Time, nineteen minutes. The patient suffered very much from vomiting for five days following the operation. Button passed on the twenty-eighth day after the operation; two stones were also passed. Highest temperature after operation, 100.5° F. This was attributed to the bronchitis.

Dr. Conley, under date of May 8, 1893, wrote me the following: "Mrs. D——, on whom you performed cholecystenterostomy, is strong and enjoying very good health. Several times within the last two weeks she has walked two miles without fatigue. There is no tenderness or pain at the seat of the operation."

Case VIII.—Mrs. B——, Rock Island, Ill., admitted to St. Joseph's Hospital May 13, 1893. Patient was very much emaciated from an illness extending over a period of six weeks. In the last two years suffered from frequent attacks of pain in the right hypochondriac region, accompanied by vomiting. These attacks were not followed by jaundice, except the last one, which began six weeks ago. This attack continued with severe pain, vomiting, great tenderness over the region of the gall-bladder. The temperature was of an intermittent character, fluctuating on every other day from 99° to 103° F. On the intervening day no temperature. The elevation of temperature was frequently, but not always, preceded by a chill.

Status Præsens.—Patient slightly icteric, very much emaciated. Pulse 120, feeble but regular. Urine contains a considerable quantity of bile; patient is nauseated when she sits upright. The attacks of pain come on every few hours and are of a distinct colicky character. There is present a tumor extending three inches below the margin of the ribs in the right hypochondriac region, and about three inches in diameter; it moves synchronously with the diaphragm in the respiratory act, and is very sensitive on pressure. It can be separated from the kidney, which is situated below and behind, and is less movable in respiration.

Diagnosis.—Cholecystitis—impaction in the ductus choledochus.

Operation by Dr. J. B. Murphy, May 22, 1893, assisted by Drs. Lee, Hartmann, and Wittwer. Cholecystenterostomy by means of Murphy anastomosis button. The operation was performed without difficulty; time, thirteen minutes. A few calculi were removed at the time of the operation.

Subsequent History.—There were no unpleasant symptoms in the subsequent course of the case; patient was discharged from the hospital on the fourteenth day after the operation. Button passed eighteen days after operation.

August 27, 1893.—Patient has increased very much in weight, is enjoying excellent health, attending to all her household duties, and has had no return of the symptoms.

Case IX.—Mary Mc——, aged sixty, widow, multipara, Philadelphia. About eight years ago she had a severe attack of colicky pain in left hepatic region; pain was intense and lasted about three days. Patient was jaundiced during this attack; she does not remember any other symptoms.

In March, 1893, she had a second attack, colicky pains in hepatic region and epigastrium, vomiting, chills, fever, jaundice; sick about one week. Patient came to Chicago on a visit last April; since her arrival she has had nearly a dozen attacks; the attacks of pain would last from six to twelve hours, and have always been followed by great prostration. The last attack began at 1 A.M., July 13, 1893. Colicky pains, great tenderness over upper half of abdomen, more marked in region of gall-bladder; jaundice, persistent vomiting. Temperature, 100–101° F., bile in urine, clay-colored passages.

July 18, 1893.—Operation, cholecystenterostomy by Murphy button, performed by Dr. F. S. Hartmann, assisted by Drs. Lee, Wittwer, and Murphy; time, seventeen minutes. After operation patient's condition was excellent, and her recovery was uninterrupted. Pulse always below 100, and good; temperature never ran above 99.8° F. Attacks of colicky pain ceased. Vomited once or twice daily for three days; vomited matter containing bile. Forty-eight hours after operation gauze drain was removed from peritoneal cavity. Bile gradually disappeared from urine, and fæces regained their color. At no time was there any great tenderness in region of operation. Button and fourteen calculi were passed at one time on the fourteenth day after operation. Circumference of largest calculus, $2\frac{5}{16}$ inches. Circumference of button, $2\frac{2}{16}$ inches. Smallest circumference of largest calculus, $2\frac{0}{16}$ inches. Patient sat up on the nineteenth day after operation. Perfect health since the operation.

August 29, 1893.—Patient enjoying excellent health, better than at any time since her second attack of colic.

Case X.—Dr. William J. Mayo, Rochester, Minn., in a personal letter furnished me the following history: "W. H——, Racine, Minn., American, male, aged seventy-one. Patient gave a history of colics for two years, jaundice for two months; great debility, cholæmia, white stools, etc.

"Operation, April 6, 1893, by Dr. W. J. Mayo, assisted by Drs. C. H. Mayo and S. Plummer. Usual incision for operation on gall-bladder. No stone found in gall-bladder; obstruction in common duct. Cholecystenterostomy by Murphy button. Bladder could not be brought to surface, obstruction could not be removed; the button was readily placed in position; no unpleasant symptoms since the operation."

This is a remarkable case on account of the age of the patient, and the doctor deserves great credit for operating on a patient so debilitated as he was at the time of the operation.

Case XI.—Dr. A. H. Fabrique, of Wichita, Kan., in a personal letter, under date of July 20, 1893, writes the following: "Enclosed please find report of patient on whom I performed cholecystenterostomy by means of your button.

"Mr. R——, aged thirty-eight, farmer, weight one hundred and eighty pounds. Had been subject to attacks of hepatic colic. Came under my observation about the middle of May, 1893. Had been suffering for two weeks previous to that time with severe pain in the region of the liver, for which he was taking one-third of a grain of morphine, three to six times a day. Jaundice all over the body for a whole week prior to the time he consulted me. I operated June 1st, found the wall of the gall-bladder so thickened that it was difficult to fasten the button into the bladder. I used the smallest button; duration of operation, thirty-five minutes. Closed the opening with silk sutures through the entire abdominal wall. Temperature did not rise any time above 99.5° F. Union per primam. There was marked improvement on the third day; skin commenced to clear up; no hepatic pain after the operation. Stools changed from white to a natural color; button passed on the twenty-first day. At the present time the man is perfectly well, pursuing his usual avocation."

Case XII.—Under date of July 20th, Dr. W. B. Rogers, of Memphis, Tenn., states that immediately after his return from the National Association of Railway Surgeons at Omaha, he had an opportunity to use the button in the operation of cholecystenterostomy, and it "worked like a charm."

The following is a synopsis of the case as furnished me by Dr. Rogers: W. A. E——, male, fifty-eight years of age. Presented in April, 1893, with all the physical signs of an enlarged liver; area of dulness occupying the epigastrium. Right hypochondriac and right lumbar regions encroaching markedly on the umbilical region. No bile in the stools. Icterus marked; emaciation very pronounced; temperature, 98° F.; pulse, 68.

Diagnosis.—"Cancer of the liver" had been repeated by several physicians and case pronounced hopeless. The enlargement of the liver was of only a few months' duration. The extreme rapidity of growth aroused suspicion of non-malignancy. Exploratory incision revealed distended gall-bladder. Eighteen ounces of muco-purulent bile, occlusion common duct, with consequent retention and congestion of liver. No evidence of malignant disease could be detected; nor could a calculus be detected in common duct. Cause of obstruction not discerned. Patient's condition urged a rapid completion of all operative procedures, hence fistula was established. Patient recovered from operation. Fistula discharged at least two pints of bile per day; icterus disappeared. General condition continued bad. Absence of bile in bowel kept nutrition below par. "After seven weeks I reopened abdomen and united small intestine to gall-bladder by means of Murphy's button; did

not attempt to close the fistula, tied thread to the button, and on the tenth day removed the button through the fistula. No reactionary fever, nor bad symptoms other than that of depression due to shock. Patient gradually improved, and at the end of eight weeks was able to be up and about the house, gradually gaining strength. Fistula has contracted, so that dressings only need changing every third day. Stool contains bile; appetite and digestion steadily growing better, and evident gain of flesh. I found the application of the button quite readily accomplished, the coaptation of parts perfect, and the results are as stated."

Case XIII.—In a personal letter to me, Dr. Alex. Hugh Ferguson, of Winnipeg, Manitoba, under date of August 14th, writes the following: "On August 3d I used your button in uniting the gall-bladder with the duodenum—cholecysto-duodenostomy. Patient passed the button on the eleventh day, and her condition is excellent. The case was difficult to manipulate owing to the short build and the large amount of fat (fully three inches) in the abdominal wall. It was a case of dropsy of the gall-bladder. One stone was removed from it, another was felt to occlude the duct."

August 28, 1893.—I received a report of this case through Dr. McArthur, of Winnipeg, who had assisted Dr. Ferguson at the operation, who states that the patient is in excellent health, and that Dr. Ferguson expressed himself concerning the button in the following words: "It is the greatest innovation in abdominal surgery since that of antisepsis."

Case XIV.—Report of operation given by Dr. J. Frank, in whose service at St. Elizabeth's Hospital it occurred. Patient admitted to hospital as a "perityphlitic abscess." Careful examination showed that it was a very much distended gall-bladder. An incision was made directly over the tumor. The gall-bladder was found adherent and was immediately incised; one hundred and forty-three stones were extracted, and the opening allowed to remain. Patient was discharged with a fistula.

Returned several months after with a large quantity of bile discharging from fistula, probed, and found stone, removed. The canal leading to bowel could not be entered. The discharge continued in large quantity and the patient was losing strength. It was decided to perform a cholecystenterostomy to allow the secretion to enter the bowel. Operation was made by Dr. M. H. Luken. An incision was made at the side of the fistula. The gall-bladder, which at the time of the first operation was a large distended sac, had now, four months later, contracted to a tube not much larger than the finger, and was adherent to the surrounding tissues. It was difficult to expose a sufficient surface of the gall-bladder to insert a button. The button was finally placed in position and the duodenum united to the gall-bladder. The button passed on the thirteenth day without pain. An operation has not yet been performed to close the external fistula. A patulous opening now exists between the gall-tracts and duodenum. The difficulty of performing the operation of cholecystenterostomy under these conditions was extremely great, and, as Dr. Frank expresses it, "I do not think that the operation could have been performed by any other means than the button."

Case XV.—Dr. F. S. Hartmann furnished me with the following history of a case that occurred in his practice:

Patient states that about five years ago he had an attack of painful stomach trouble, took sick gradually, complained of pain and soreness in all his bones, thinks he had fever with this attack, no nausea or vomiting, suffered from constipation. The illness lasted about one week; the patient is unable to give any other facts in connection with this attack. On August 23, 1893, patient experienced a dull aching pain in pit of stomach which lasted two days, and then suddenly became much worse and of a colicky nature; was accompanied by persistent vomiting of bile and mucus. The colicky pain lasted two days and was very intense. Patient has had eight similar attacks since the attack of August 23d.

A characteristic feature of all his attacks has been the peculiar manner in which three symptoms followed each other. 1, Acute colicky pain; 2, a burning sensation in chest and throat; 3, persistent vomiting. He suffered from digestive disturbances for fifteen years. During an attack occurring September 29, 1893, a trace of bile was found in the urine; patient was never jaundiced; no calculi were ever found after an attack.

Diagnosis.—Cholelithiasis. Obstruction of cysticus. Operation by Dr. F. S. Hartmann, assisted by Drs. Murphy, Wittwer, and Lee, October 26, 1893. Cholecystenterostomy by means of Murphy anastomosis button. Time for insertion of button, seven and one half minutes; time for entire operation, twenty six minutes. Convalescence uneventful. Button passed on the ninth day.

Case XVI.—W. B——, aged forty years; cigar maker. Three years ago had first typical attack of gall-stone obstruction, accompanied by jaundice. Since that time had had five similar attacks: last one began about two weeks ago; was less severe than previous attacks. Operation by Dr. Murphy, November 7, 1893. Cholecystenterostomy by means of Murphy button (smallest size). Gall-bladder was found distended; gall-stones not removed. Time from beginning of operation to completion of anastomosis, eleven minutes. Patient acted very badly under anæsthetic (ether). Had some bronchitis following operation; aside from this his convalescence was uneventful. Was about the ward in three weeks. Jaundice had completely disappeared.

Case XVII.—Reported to me by Dr. D. T. Laine, of Media, Pa. Mrs. L——, aged forty-five, married, one child; October, 1892, was attacked with intense abdominal pain, paroxysmal in character, vomiting, and constipation. Jaundice appeared on second day, stools clay-colored. Severe chill on sixth day with temperature of 104° F. The jaundice was of the most marked type, and the chill and fever persisted for several days. Patient was sent to Jefferson Hospital. Diagnosis of obstructive jaundice. She remained in the hospital for nineteen weeks, chills and jaundice persisting, with rapid emaciation. Professor I. C. Wilson had Drs. Keen and Brinton in consultation. They decided that, on account of the woman's weak condition and the possibility of the malignant character of the trouble, an operation was not advisable. Jaundice and fever disappeared. She was discharged February 1, 1893, and remained well until July 15th, when the vomiting, chills, and fever returned.

Dr. Laine at that time performed a cholecystostomy in two sittings. Removed one large calculus marked with many facets. Explored common duct through foramen of Winslow. Found no stone. Temperature dropped immediately, and in a month she was about, tending to her usual occupation. The stools remained clay-colored and she suffered much from gaseous distention of the bowels, also the enormous discharge of bile externally.

On September 20th, Dr. Laine determined to close the fistula, at the same time performing cholecystenterostomy, which he did with Murphy button (smaller size). Fistulous tract was curetted and closed with a circular stitch. The abdominal wound was closed without drainage. The temperature remained between 99.5° and 100° F. for several days; she made an uneventful recovery. Since then she has been in very good health, able to attend to all her duties. Gained about twelve pounds. Button found in stool on the twelfth day.

INFLUENZA—CAUSES, COMPLICATIONS, AND TREATMENT.[1]

By RAMON GUITERAS, M.D.,

NEW YORK.

History.—Influenza, or la grippe, is probably richer in names and symptoms than any other known disease. I will mention a few of the former by the way of illustration. They are: Epidemic catarrhal fever, rheuma epidemicum, cephalalgia contagiosa, Ziep Schaf husten, Hühnerweh, Blitz catarrh, Russian disease, Italian fever, Spanish catarrh, etc., depending mainly on the variety of symptoms and the locality from which it comes.

We often have the question asked us "What is Influenza?" I think that a safe answer to this would be, It is an epidemic cold depending upon some as yet unknown cause.

Colds have a tendency to settle in certain parts, generally the weaker ones, and influenza does likewise. The systemic symptoms occur in varying severity in all its varieties, while the catarrhal symptoms cluster about certain organs where the power of resistance seems to be naturally least. These epidemics date before the Christian era, an attack having occurred in the Athenian army in Sicily 415 B.C. After this they began to appear at irregular intervals, spreading over Europe generally in the direction of from east to west, of which no exact or complete records have been kept up to the year 1510, when it prevailed in the British isles to an alarming extent and quite an accurate account of the epidemic was written. Various well-recorded outbreaks followed in the years 1557 to 1879, about twenty in all, besides others of minor importance. These varied in severity, symptoms, number, and suddenness of the attacks.

Etiology.—Predisposing influences, none. People are attacked without distinction of age, sex, occupation, or social standing. Previous or present illness affords no protection. One attack renders no immunity from another. Overcrowded, unhealthy, badly ventilated, and damp dwellings render attacks more severe, although the dwellers are no more prone to it. Influenza may occur in any season. It occurs usually in the autumn, often in the spring, and sometimes in the summer and winter. Latitude has no effect, as in the epidemic of 1837 it appeared at the same time in England and Cape Colony, that is, in directly opposite zones and seasons. Climate has no influence, as it occurs equally in the dampest and driest regions. Certain meteorological signs and coincident phenomena have been remarked as preceding many of the previous epidemics, such as foul fogs, volcanic eruptions, earthquakes, etc.

The rapidity with which it spreads and the great numbers who suffer from it at the same time and in the same

[1] From observations made while investigating this disease for the Health Department of the City of New York.

way certainly point to some specific poison which is carried by the air as a disseminating medium and excites the disease. This poison was supposed by many for a long time to be the sulphur and other matter thrown from the volcanoes, which was carried about in dust-fog currents, a foul fog having been generally noticed before an epidemic, or accompanying it. In this enlightened age, however, I think we are justified in believing that the exciting cause is a micro organism.

The investigations of the bacteriologists in searching for micro organisms have resulted as follows:

For several years the diplococcus pneumoniæ of Fraenkel and Weichselbaum, the streptococcus pyogenes, the staphylococcus pyogenes aureus, and several scattering forms were the only ones found, until Dr. Pfeiffer, of Berlin, in 1892, discovered a bacillus in the secretions of patients suffering from influenza, which was declared by Koch, Kitasato, and others to be the true germ of this disease. This bacillus was about the thickness of bacillus mouse septicæmia, but only half the length. As only the two ends stain, it is very hard to distinguish it from the diplococcus and streptococcus. Former observers seeing these mistook them for the latter. They were cultivated by Kitasato and others.

About the same time Bruschettini[1] found the same germ in the blood of those suffering from the disease.

The question why an epidemic may break out at one time and then for years remain dormant is not an easy one to answer. It is probable that there are cycles in which peculiar seasons recur, and that such cycles are associated with the reproduction of similar disordered conditions in the health of man.

Symptoms.—There is no disease in which the characteristic symptoms vary as much in the various epidemics as they do in influenza, and there is also no other in which the symptoms vary so much in point of predilection and severity. The predilection depends upon individual weakness and the susceptibility of certain systems, as the nervous, respiratory, alimentary, genito-urinary, etc., to disease. The severity depends in a great measure on the condition of the patients, at the time of the attack, as to their resisting powers, the amount of exposure to which they have been subjected, the character of the epidemic, etc. Almost everyone during an epidemic is attacked, although some suffer to such a limited degree, as a slight headache, gastric disturbance, or a feeling of languor, that they think they have escaped. The varieties of the attacks during the different epidemics have given rise to several classifications, depending upon the different seats of the disturbance, *e.g.*, cephalic, thoracic, abdominal, cerebral, guttural or bronchial, intestinal or typhoid. This latter was the classification of Sydenham, and depended upon epidemics extending over a period of three hundred years. The classification preferred at the present date seems to be that of the nervous, catarrhal, and gastric; and this was the classification that I adopted in my last writings. At the present date, however, having watched the epidemics carefully during the last few years, I am inclined to classify the varieties into two chief groups, and to subdivide them accordingly. In doing this I strike out the gastric variety, placing it under the catarrhal. The classification would then consist of but two principal varieties, viz.: 1, Musculo-neuralgic; 2, catarrhal; and these I believe are mixed in about ninety per cent. of the cases. Musculo-neuralgic symptoms almost always complicate the catarrhal form, although catarrhal do not nearly as often complicate the musculo-neuralgic.

These varieties, with but few exceptions, have the same general symptoms and tend to conclude in the same way. They are:

Onset: Feeling of weakness, faintness, dizziness, chilly sensations, constipation, perhaps nausea, vomiting, anorexia, languor, or high fever.

Acute stage—lasting from a few hours to a week, during which we have frontal headache, often pain in orbits and eyeballs, loss of appetite, strength, and spirits, feeling of languor, lassitude, inability to do any mental or physical work; rheumatic pains variously distributed in back of neck, small of back, costal region, or calves of legs; bowels may continue constipated; urine high colored; foul tongue and breath; fever generally continues, of a remittent type, with evening exacerbations.

Stage of prostration—lasting from a few days to a few weeks, marked by nervous prostration, general feeling of languor, poor appetite, and generally a bronchitis of a dry nature. In children and infants the symptoms are not as marked.

In children they are as follows: Vomiting, headache, moderate fever, coated tongue, constipation, followed by a bronchitis lasting about a week. In infants symptoms of gastro-enteritis, vomiting, diarrhœa, moderate fever, rapid pulse, and occasionally convulsive movements.

We will now consider the varieties individually and point out the special features of each.

Musculo-neuralgic variety: This variety is generally associated with the catarrhal as well, but when taken individually is especially marked by severe headache, pain in the eyeballs, rheumatic or neuralgic pains in various localities, restlessness, at times wakefulness, occasionally hyperæsthesia, and following these a stage of great nervous prostration, lassitude, languor, sweating, etc.

The catarrhal variety is characterized by symptoms pointing to a congestion of certain organs or their mucous tracts, and is divided into three principal groups:

1. The respiratory, which is the form that has hitherto been called catarrhal, guttural, bronchial, or thoracic.

2. The alimentary, embracing the varieties spoken of as gastric, intestinal, abdominal, or typhoid.

3. The genito-urinary, which has never before been considered.

A general catarrhal also occasionally occurs, in which form the symptoms included in the first three groups are combined in varying severity in one attack.

These groups are further subdivided according to the locality from which the symptoms arise.

The respiratory-catarrhal form is generally marked by a catarrh beginning in the upper respiratory tract, with pain in the frontal sinuses, eyes painful, congested, and watery, profuse and watery nasal discharge, feeling of stenosis over the bridge of the nose, marked angina, occasionally tonsillitis, tickling in throat, hoarseness, ending in a bronchitis lasting from a few days to several weeks. Epistaxis and hæmoptysis occasionally occur. When, as is rarely the case, it is limited to the upper respiratory tract, we have only the symptoms usually accompanying nasal and pharyngeal inflammations.

The catarrh of the middle respiratory tract is that localized in the pharynx, larynx, and trachea, principally in the latter, the former generally being inflamed sympathetically. This is characterized by a hoarseness and sense of excoriation and tickling in the trachea (tracheitis), a feeling of laryngeal thickening producing a spasmodic cough corresponding to that of croup in children. In other cases it resembles more a bark of the variety known by the Germans as Schathusten. In still others it has a whistling note. In the catarrhal variety of the lower respiratory tract a bronchitis generally follows or is associated with the upper or middle respiratory form. It is a peribronchial congestion, giving rise to a troublesome spasmodic cough. Auscultation shows roughened breathing, fine subcrepitant râles, often sonorous and sibilant over both sides. Pulse, temperature, and respiration slightly elevated, but going down gradually to normal. Fever often remittent. Neuralgic symptoms generally associated with it.

Alimentary.—In the gastric form we have violent and frequent vomiting, nausea, pain, loss of appetite, constipation, often severe headaches, faintness, and dizziness.

The gastro-intestinal form has, in addition to the vomiting and other symptoms of gastric disturbance, a

[1] Ricerche bac. sull. infl. 1ª communicazione preventiva. Riforma Medica, Gennaio, 1892.

diarrhœa of the usual form that accompanies a subacute gastro-enteritis.

The intestinal form is principally a colitis accompanied by marked tenesmus, stools diarrhoeal in character, often mixed with mucus and tinged with blood. Dysenteric symptoms of a very grave nature occasionally set in, causing death in a few hours.

The genito-urinary variety is a rare form, generally of a mild type and frequently not known to the person affected. My attention was first called to it by the great number of applicants for insurance who had to be postponed during the epidemics on account of high specific gravity and albumin. These I found to be suffering from influenza. Their symptoms constitutionally were the same as those suffering from the respiratory or alimentary form. The condition was generally localized in the kidney, and the urine showed the ordinary symptoms of renal hyperæmia, *i.e.*, high colored, high specific gravity, albumin in small quantities, blood-corpuscles, and occasionally hyaline casts. This condition usually lasted but for a few days.

The vesical type was similar to that of cystitis of the vesical neck. It was very rare. Constant desire to pass water, pain over pubes, and a sense of heaviness in the perineum. Urine high colored, high specific gravity, some mucus.

The urethral and vagino-urethral forms were still rarer, and were accompanied by a watery, glairy, mucoid discharge, attended by a congestion of the parts and burning during micturition. These were generally combined with some other forms of the genito-urinary catarrhal variety. They are very rare and ephemeral.

General catarrhal fever, i.e., catarrh of all the mucous membranes, was observed in several cases, characterized by high fever, rapid pulse, vomiting, diarrhœa, painful and frequent urination of a dark-red color, with a high specific gravity and a slight amount of albumin, slight conjunctivitis, coryza, laryngitis, and bronchitis. The attack was generally very acute, though of short duration.

Complications.—By far the greater number of complications and the most serious are those connected with the respiratory form, which I will mention in order, going from above downward.

Conjunctivitis is generally associated as a symptom with the upper respiratory variety.

Epiphora due to stenosis of duct.

Epistaxis occurs in about two per cent. of the cases. Occasionally it is quite severe, and in some cases has continued for twenty-four hours.

Follicular tonsillitis has been observed in several cases.

Quinsy, complicating many previous epidemics, has not been observed in the recent ones.

Eustachian catarrh and otitis media are complications which exist in a great many cases, and are at times only noticed by the specialists, general practitioners frequently attributing the symptoms to the neuralgic pains of the disease, or to a sense of fulness due to quinine, which is being taken by almost all influenza patients; and thus ruptures of the tympanum have occurred in many cases where paracentesis ought to have been performed.

Loss of the senses of smell, taste, and hearing sometimes occur, evidently due to a peripheral paralysis of the nerves of special sense.

Glandular enlargements have not been prevalent during the recent epidemics, probably owing to the mild forms of catarrh in the upper and middle respiratory tracts. There are two varieties of these. Enlarged cervical, such as occurred in former outbreaks, where the catarrhal symptoms of the upper respiratory tract were principally involved, and which were often very malignantly inflamed. Enlarged bronchial and tracheal glands (adénopathies bronchiques). These cause a feeling of thickening and packing about the upper bronchus and trachea, the latter having a board-like feeling. A sense of soreness is also connected with it, both bronchial and peribronchial. These glandular enlargements can be made out by percussing after the method of Gueneau de Mussy.

Hæmoptysis was observed only in a few cases and was very slight.

Capillary bronchitis and bronchitis of the smaller tubes are complications of the ordinary form of bronchitis by direct extension. They generally occur in women and at any age. They are very fatal, the great prostration seeming to affect their power of expectoration so that they "choke up" and die asphyxiated. These are often followed or complicated by a lobular pneumonia.

Lobular pneumonia is very acute, lasting from three to seven days. It generally occurs in the old, the middle-aged, and the sickly, although young adults are frequently affected. It seems to be most common among females. A chill sometimes introduces this complication; in fact, I have noticed a chill in this variety more frequently than in any other. It begins at the bottom of the lung and spreads upward. Death results either from heart-failure or asphyxiation.

Lobar pneumonia generally attacks patients during the stage of prostration, is frequently double, comes on generally without a chill, and is accompanied by a very high fever. It occurs generally in men, eighty per cent. of those observed were between the ages of forty and fifty-five. Death is usually from heart-failure and occurs in from two to five days.

Grippe-pneumonia is a form often spoken of, and is a condition following a pulmonary congestion. It is generally in both sides, comes on insidiously without being accompanied by a chill or the crepitant râle as in ordinary cases. The consolidation usually begins at the base or the middle of the lung.

Pulmonary hyperæmia is a frequent and dangerous complication, and occurs with much greater frequency than it is supposed. This should be treated at once with the greatest care, and every precaution taken lest it develop into a grippe-pneumonia. It is very similar to lobar pneumonia in its early stage, excepting that it is less severe and covers a greater area. It is due to a recession of blood from the surface, or from some other adjoining organ, to the lungs by reflex action through the vaso-motor system. The lungs seem to be most favorably adapted for such a congestion on account of their great vascularity and the lack of resistance to the dilatation of the capillaries in comparison with that found in other organs. Just why this particular disease, influenza, happens to produce such a congestion is difficult to explain. It is obvious, however, that it holds the respiratory tract as a seat of predilection, as almost all its forms are accompanied sooner or later by a congestion either of the upper air-passages or a peribronchial one of the lower, although an active hyperæmia of the parenchyma itself is comparatively rare. Diarrhœa occurs in many cases, but is simply the intestinal form of the alimentary variety.

Dysentery is a dangerous form of the colitis occurring in this same variety. In the two cases which came under my observation death resulted in two days. In both cases the first day's discharges were simply diarrhœal.

Cholera, a sequela which is so much feared, especially in Europe, will probably never make much headway here. It does follow influenza, and has during the last two years. It can be more easily guarded against, however, than influenza, as it is more distinctly contagious. It is more liable to attack those who have suffered from the gastro-intestinal form of the disease, which often occurs and leaves the mucous membrane in a somewhat denuded condition.

Typhoid fever as a sequela has not been observed in any fatal cases in New York during the late epidemics, but the typhoid condition has been noticed frequently, and has been observed especially in some cases of dysentery, bronchitis, and broncho-pneumonia.

Meningitis has occurred in a number of cases, death resulting in about two days.

Nervous prostration, which is such a pronounced symptom in the various stages of influenza, has proven a

most obstinate sequela. Acute hyperæmia of the tongue has also been observed. The tongue was enlarged, reddened, hard, and tender to such a degree that the pressure of the teeth against it was quite painful. The tongue felt too large for the mouth and protruded, resting on the lower teeth. The papillæ on either side were enlarged and sensitive.

The Various Dermatosis of Influenza.—The principal one of these is the erythema (influenza erythematosa). This generally occurs with influenza of the gastric type, during its acute stage, and closely resembles scarlet fever. It comes on as a pinkish blush over the face, chest, and arms, and is not punctate. The tongue has a thick, white coating, with enlarged papillæ on the sides near the tip. The skin is moist. Miliaria occasionally occurs. Erythema multiforme is also seen in this connection. Alopecia areata has been reported as a complication. Herpes zoster was observed by me in two cases during the last epidemic.

Diagnosis.—The only diseases with which influenza is liable to be confounded are coryza, bronchitis, tonsillitis, dengue, scarlatina, and rheumatism.

Acute coryza and bronchitis would be excluded by the absence of severe headache, muscular pains, great prostration, and anorexia, although doubtless if these occurred during an epidemic they would be more or less due to it, and most probably mild in form. Follicular tonsillitis has many symptoms in common with influenza, but would be excluded through the absence of severe frontal headache, rheumatic pains, etc.; although I have every reason to believe that follicular tonsillitis has occurred in several cases of influenza as a complication.

Dengue resembles in a great measure the muscular neuralgic form of the disease. It would be excluded, however, on account of the different character of its onset—it generally taking from two to three days for the temperature to reach its height—the character of relapse, the eruption, the pain, swelling in joints, the enlarged glands, etc.

The rapidity with which the influenza has travelled and the territory which it has covered differ also from dengue, which occurs generally in circumscribed areas in the south of the United States, Spain, India, or Africa.

Scarlatina.—This disease, with which the late epidemics have been most confused, is excluded on account of lack of punctate character to the eruption, strawberry tongue, and angina; also on account of speedy disappearance of the eruption, which lasts about twelve hours. The eruption, however, is quite similar in its general erythematous blush, and when it is associated with some angina and high fever the resemblance is quite strong, especially as the tongue shows some enlarged and reddened papillæ on its sides near the tip, which stand out prominently in contrast with the white coating covering it.

Prognosis.—Good in most of the cases. The disease is self limited, and if the patient is careful there is no question of speedy recovery. The only danger is when it occurs in the old and the infirm, or those suffering from chronic troubles. One thing noticeable in the last epidemics was how few phthisical patients, comparatively speaking, have died from its effects, although in many cases they have succumbed from intercurrent bronchitis. In Bright's disease and valvular disease of the heart the influenza is more fatal. A few deaths were due directly to the disease, but these occurred in cases of old age, tumors, and other cachectic conditions, in which the patient died within twelve hours, probably from the shock of the sudden onset. In two other cases of feeble women, death occurred in two days, due to heart-failure.

Treatment.—Rest in bed during acute stage. Patient should remain at home until temperature is normal. It would be advisable for them to remain in the house until entirely well, but as they generally will not do this, it is important that they should remain at home evenings. They should be very careful in regard to their clothing, the wearing of rubbers, overshoes, etc. They should avoid all draughts of air, as in the stage of prostration and sweating they are very susceptible to pulmonary complications. They should ride in cabs, if possible; if not, in horse-cars, or the front or rear car of the Elevated.

At onset move bowels, calomel two grains every two hours until they have moved, or two compound cathartic pills in one dose. At bedtime, quinine and Dover's powders, with a hot whiskey punch.

For headache, fever, and muscular and neuralgic pains, give antipyrine, ten grains every two hours, with whiskey, one-half ounce, until the headache is relieved. Two of these powders will generally be sufficient to relieve the most obstinate. It is not advisable to give more than three of them, but in case they do not produce the desired effect, to change to antifebrin or phenacetin, in five-grain doses, every two hours. Whiskey should be given with these drugs, as it hastens their action and tends to counteract their depressing effect. In case the muscular pains are obstinate, salol, in five grain-, or salicylate of soda, in fifteen-grain doses, three times a day, will generally relieve them.

Great anorexia and weakness being present, milk-punches should be given every two hours, if well borne, during the acute stage.

In all stages of the disease whiskey is the remedy *par excellence* to counteract the great prostration, and should be taken three times a day throughout the attack. If whiskey is not well borne, give champagne, brandy, or sherry. Quinine is also a standard remedy, and is useful both as an antipyretic and a tonic. During the acute stage it should be given, if the stomach can bear it, in five-grain doses three times a day, and in the stage of prostration following it should be given, purely as a tonic, in three-grain doses, in combination with nux vomica and iron in pill or solution. In the alimentary forms, where there is considerable vomiting, good results have followed a milk diet, with a powder of bicarbonate of soda, pepsine, and bismuth, ten grains of each every four hours. If diarrhœa is present add one-eighth to one-tenth of morphine to each powder and increase in frequency if necessary. All very sick cases should be put on a milk and whiskey diet—two and a half quarts of milk and four ounces of whiskey a day.

In catarrh of the upper respiratory tracts a pill of belladonna, camphor, morphine, and quinine every two or three hours gives speedy relief. In cases of pharyngitis and tonsillitis an astringent spray or gargle should be added.

When the laryngeal and tracheal symptoms are most pronounced inhalations of tr. benzoin comp. afford the most relief. In bronchitis of the dry and semi-asthmatic form, which generally occurs, and which seems to be more of a congestion of the bronchial mucous membrane with a spasmodic cough, a mixture containing belladonna and morphine will give great relief. A preparation of codeia, gr. one-sixth; am. iodid., gr. three, in mist. expect. Stokes, ʒ j., every three hours is also very valuable in the treatment of this bronchial condition. In case of bronchitis with abundant secretion, muriate of ammonia or the more stimulating expectorants must be given. In the genito-urinary variety simply place the patients on a milk and Vichy diet, and confine them to the house. Complications should be treated accordingly, and digitalis and strychnine should be given in cases where the heart-action is weak, to prevent heart-failure, as influenza seems to have a depressing influence on the heart-action.

In the musculo neuralgic variety of influenza we have a specific in the pill of phenacetin and salol, two and a half grains of each every three hours.

When severe nervous prostration follows, a tonic consisting of the phosphates, with quinine, iron, and strychnine, should be given. The phospho-muriate of quinine (Phillips's tonic) is excellent in these cases.

In conclusion, after having observed so many cases

during the almost annual epidemics of the last few years, and so many sporadic ones between the epidemics, I think we have abundant ground for suggesting the possible advent of a new disease of an ephemeral nature.

79 West Fifty-fourth Street.

Progress of Medical Science.

Prolonged Intermittent Treatment of Syphilis.—At a meeting of the Medical Society of Vienna, Professor E. Lang read a paper (*The Medical Week*, November 24, 1893) in which he criticised the treatment of syphilis advocated by Professor A. Fournier, of Paris, who has now been induced, as the result of a long experience, gradually to increase the duration of the treatment from nine months, as recommended by him several years ago, to five or six years. The author is of opinion that the method devised by the distinguished French syphilographer is not in conformity with the natural evolution of syphilis. Syphilis being a curable affection at any stage of its development and even before the appearance of the secondary manifestations, it is evident that no single method of treatment will do in all cases. The therapeutical means employed must necessarily vary according to the necessities of each individual case. In a recent publication (*The Medical Week*, 1893, Vol. I., p. 35), Professor Fournier gives some statistics based on 1,703 cases of tertiary syphilis which, from the point of view of the duration of the treatment, may be classified as follows:

	Cases.
No treatment	217
Treated for less than one year	1,162
" from one to two years	265
" for more than two years	53
" for more than three years	6

Professor Fournier concludes, therefore, that out of 1,703 cases of tertiary syphilis, only 59 occurred after, and in spite of, conscientious treatment, while in the remaining 1,644 cases the accidents were due to the fact that the patients had only been very imperfectly treated, if at all.

Professor Lang pointed out that supposing Professor Fournier still believed that twelve months' treatment were sufficient to cure syphilis, he (Professor Fournier) would be obliged to admit, in the presence of the foregoing statistics, that tertiary manifestations occurred in two hundred and seventeen patients who had not been treated, and in 324 (265+53+6) who had been submitted to appropriate treatment for the requisite period of time. The obvious conclusion would then be that, so far as the tertiary manifestations are concerned, prolonged treatment is worse than total absence of treatment.

To show that cerebral syphilis can be prevented by his method, Professor Fournier quotes 100 cases of syphilis of the brain which can be tabulated as follows, according to the duration of the treatment:

	Cases.
Prolonged and conscientious treatment	5
Treatment of average but insufficient duration	6
" for from seven to eighteen months	10
" for from one to six months	70
No treatment	4
Treated by iodide of potassium alone	5

This table shows, according to Professor Fournier, that "only 5 out of 100 cases of cerebral syphilis had been submitted to conscientious treatment, while in the remaining 95 cases the treatment had been *nil*, or only very imperfect, or of short duration; from which it follows that cerebral syphilis is nineteen times less frequent after conscientious treatment than in patients who have not been treated at all or only very imperfectly."

This statement is open to the same objection as the statistics already quoted, and Professor Lang believes that the following conclusions may equally well be drawn from the facts brought forward by Professor Fournier, showing how far the figures given by the eminent specialist are deceptive:

1. Five patients out of one hundred have taken nothing but iodide of potassium as against ninety-five who have either not been treated at all or have been submitted to some other method of treatment; from which it follows that cerebral syphilis is nineteen times less frequent in patients who have been treated by iodide of potassium alone than in those who have taken mercury or nothing at all.

2. In four cases out of one hundred no treatment was applied, while in the remaining ninety six mercury or iodide of potassium was administered; from which it follows that cerebral syphilis is twenty-four times less frequent in cases in which no treatment is employed than in those in which mercury or iodide of potassium is administered.

Indeed, Professor Fournier himself admits that he has met with cases of recovery from syphilitic disease of the brain in which the patients had undergone a prolonged course of treatment, as well as with cases in which the patients remained free from specific manifestations of any kind, eight, twenty-four, and even thirty-four years after a short period of treatment.

So far from exerting a favorable influence in cases of syphilis, the method of prolonged treatment recommended by Professor Fournier is apt, according to the author, to produce a deleterious effect on the patient's general health by giving rise to various alimentary troubles associated with insomnia and other nervous symptoms of a somewhat grave description, and favoring the occurrence of tertiary manifestations. For example, the statistics communicated by Professor Fournier to the First International Congress of Dermatology, in 1889, show that the liability to tertiary manifestations increased in his patients until the third year after infection, a fact which is in direct opposition to the experience of the advocates of the "opportunist" method who have never met with the same liability to tertiary accidents during the first three years after infection in the patients under their observation.

The statistics communicated by Professor Fournier to the Congress were based on a series of 3,429 cases, in 1,085 of which the nervous system was the seat of syphilitic lesions, a very large proportion, even after deducting the 355 cases of tabes, which are regarded by the distinguished French syphilographer as of syphilitic origin.

Lastly, Professor Lang pointed out that Professor Fournier has never reported a single case of reinfection in patients treated by his method, the occurrence of reinfection being a most conclusive proof that the patient had been completely cured of his first attack of syphilis. Another disadvantage of the prolonged treatment consists in the fact that certain patients are very liable to relapses irrespective of the method of treatment to which they are submitted; if such patients are already under the influence of mercury, the administration of this remedy is not attended by the same success as it would be under other circumstances.

The Vaso-motor Apparatus in the Vaccinated and Tolerance of the Toxins.—At a recent meeting of the Paris Biological Society a communication on this subject was read by Drs. Gley and Charrin. From the moment that it was demonstrated that microbes were the cause of disease, either through their own influence or their secretions, it must have occurred to some that immunity might be a simple question of tolerance. As a matter of fact, it has been maintained that the reason why the introduction of bacteria into the tissues and organs was not followed by grave accidents in the vaccinated, was because the cells and tissues of these individuals were rendered insusceptible to the action of the substances secreted by the microbes, as a result of the tolerance produced by vaccination. This opinion is now untenable in view of the experiments of Gamaleïa and Charrin, experiments which have been verified by various investigators. The absence of grave manifestations in the vaccinated after inoculation is due in reality to the fact that the micro organisms are unable

to grow and develop with sufficient activity to give rise to such manifestations; as a result, the essential condition for infection, viz., the presence of a large dose of an active virus, is wanting; the symptoms of intoxication are not observed because of the absence of the poison, or its presence in infinitely small quantities, the activity of the microbes by which it is produced being interfered with by phagocytosis, the bactericidal properties of the humors, and other causes. It has also been maintained that, although taken as a whole, the tissues of the body exhibit no special tolerance to the action of pathogenic bacteria; yet it would be very different if the influence of the virus were exerted on only one of the different systems, for example, on the most delicate of all, the nervous system. Nervous disturbances of a motor or vaso motor character (pyocyanic paralysis, vaso-constriction) were experimentally produced for the first time by injecting the toxins of the bacillus pyocyaneus. These disturbances, which are due to the action of this organism or the products of its secretion, have since been reproduced by various investigators with other bacterial poisons. The paralytic manifestations are usually of slow development. This is a drawback from an experimental point of view, hence we have been induced to direct our researches in the direction of the vaso motor apparatus. The vaso-constricting properties of the pyocyanic toxins were first discovered by Professor Bouchard, who succeeded, by an injection of these toxins, in relieving the congestion produced by tuberculin. We have shown that this phenomenon was due to the paralyzing influence of these secretions on the vaso dilating centres. For example, stimulation of the auriculo temporal nerve is followed by congestion of the ear in rabbits; this phenomenon is known as the Snellen-Schiff reflex. By injecting a definite dose of a sterilized culture of the bacillus pyocyaneus into the circulation of the animal this hyperæmia is retarded or, at any rate, a more powerful current is required to produce the same result. If the experiment be performed simultaneously on vaccinated and non-vaccinated rabbits, exactly the same reaction is observed to take place in all the animals experimented upon. In all of them the reflex is excited, under the same conditions, after the same lapse of time, with the same degree of intensity, and by means of currents of the same strength.

We are justified in concluding, therefore, that the vaso-motor system is as sensitive in vaccinated as in non-vaccinated animals; in other words, that in the former the system in question shows no special tolerance of the toxins of the bacillus pyocyaneus, thus furnishing further evidence against the theory of immunity through tolerance. We do not wish to imply, however, that this remark applies to all cases. It is possible that things may be different with other toxins administered under different circumstances. Immunity depends on a number of variable factors. In diphtheria, for example, we have the formation of antitoxins which neutralize the effects of the toxic products, but this cannot be regarded as the result of tolerance on the part of the individual, as used to be erroneously maintained by certain observers. Moreover, experiments on other animals with purer substances or only with some of the ingredients of these substances, may possibly lead to results different from ours, although we may point out that we have experimented without success with the dead organisms, proteins, volatile products, and products soluble in alcohol. In these experiments we have endeavored as far as possible to work only with small quantities of the substances above enumerated. It is evident, however, that in this respect we cannot hope to reproduce exactly what takes place in the tissues of the animal inoculated with the living organisms. In the latter case the tissues are acted upon by fractional doses of the toxic products which are being constantly secreted. We are perfectly willing to admit the value of all these objections. What we maintain is that the vaso motor nervous system of rabbits vaccinated against the bacillus pyocyaneus is equally sensitive as that of non-vaccinated rabbits to the influence of sterilized cultures of this organism in meat broth; we are justified in concluding, therefore, that tolerance is not acquired by vaccination.—*The Medical Week.*

Pregnancy after the Removal of One Ovary and Part of the Other.—Sippel reports a double ovariotomy in a woman thirty years of age, who had one child five years old and was very anxious for another. The right ovary was converted into a tumor the size of a child's head, and without a trace of normal ovarian tissue. This was removed with its tube. The other ovary was the size of a goose egg. Along the hilum was a long tract of normal tissue. A clamp was applied above this tract to check hemorrhage, and the diseased part of the ovary was cut away; the raw surfaces left were united by means of catgut sutures, while some blood-vessels were tied separately. This healthy part was an inch and a half long and a third of an inch thick; the left tube was undisturbed. Menstruation returned after the operation, and ceased on August 22, 1891; on April 7th pregnancy was progressing favorably, and she was safely delivered of a living child.—*Archives of Gynecology.*

Disappearance of Gonorrhœal Discharge During Pneumonia.—Dr. Bogdan has recently observed the following case in a young man, aged eighteen, who was received in the hospital for the treatment of a gonorrhœa with profuse and purulent discharge and violent pains before and after urination. Four days after admission he developed pneumonia of the left lung, and the next day he noticed that the discharge had ceased, together with the other symptoms. On the tenth day, on the beginning of convalescence from the pneumonia, the gonorrhœa reappeared in all its original intensity. Dr. Barthélémy has seen two similar cases. In both the urethral discharge disappeared after the beginning of an attack of typhoid fever. One of these patients died on the eighteenth day of the disease, without the affection again being observed, while the second was seized on the seventh day, without having left his bed, with a severe epididymitis, which would lead one to think that the gonorrhœa had only apparently been cured.—*Wiener medizinische Presse.*

How to Incise Post-pharyngeal Abscess in Children.—Dr. Pitts states that compression of the trachea in the neck may be caused in children by abscess, by enlarged glands, by goitre, or by a foreign body impacted in the œsophagus. Abscess in the neck, producing compression of the trachea or inflammatory œdema of the glottis, is most likely to be post-pharyngeal in position. The advantage of opening a post-pharyngeal abscess by incision in the neck, and not within the mouth, is now fully recognized, particularly if the abscess is dependent on vertebral disease and the discharge is likely to be continuous (*The Lancet*). If the difficulty of breathing is urgent and the dissection from the neck likely to be too prolonged, tracheotomy will be advisable as a first step. Intubation would seem to be contra-indicated by the possible alterations in the relations of the larynx and trachea. If, however, the abscess is small and there seems to be a difficulty in getting at it from the side of the neck, a vertical incision may be made from the mouth; but care should be taken to bend the child's head quickly forward so that the pus may run out of the mouth. If radical treatment is postponed, pressure symptoms may become urgent, or rapid œdema of the glottis may arise, or the abscess may burst spontaneously and death take place by suffocation, particularly if the abscess should burst while the child is asleep. In children under a year old these abscesses do not often depend on cervical caries, but arise from causes which produce similar abscesses elsewhere, such as inflammation around the lymphatic glands in front of the vertebræ; or they are secondary to tonsillitis, disease of the ear, or after catarrhal conditions of the posterior nares and fauces. In two hundred and four cases, which were recorded by Bokai as occurring in the Children's Hospital at Pesth, only seven were secondary to caries of the vertebra.

BOARD OF HEALTH AND PERSONAL RIGHTS.

THERE is no doubt that before long many cases will come before the courts in which the question of personal and private rights as against the interference of Boards of Health will be raised. Compulsory vaccination, for example, is being gradually extended so that not only school children, but factory employees, clerks, and even opera troupes, are visited by the health officials with needles and vaccine. The law, as we understand it, does not directly compel vaccination, but forbids attendance at school, and even employment in large factories, unless the individuals have been properly protected against small-pox. At the present time some of the factory employees object to the operation for fear it may make them sick so that they will lose their work. It seems to us that the time has come when the statutes regarding vaccination should be more definite and explicit. Either vaccination is a safeguard or it is not; if it is, as we believe, then there is no reason why it should not be generally and directly enforced.

More important questions, perhaps, arise in connection with the abatement of nuisances. And here the law has been recently interpreted in the case of the People *v.* the Board of Health of Yonkers. The Court of Appeals has decided, in effect, that Boards of Health have the right to abate a nuisance; but the individual, on the other hand, has the right to have a trial as to whether the nuisance really is such. If it be decided that it is not, and the Board of Health is found to be mistaken, the citizen is protected and he has the right to receive compensation for damages inflicted.

In some cases the State voluntarily furnishes compensation for injury inflicted upon property, and this is often most wise and just.

POLITICS IN MEDICINE.

IN anticipation of the coming meeting of the Medical Society of the State of New York, at Albany, next month, it is desirable to call the attention of such as may be present to the proposition made at the last session to alter the by-laws so that the President could be nominated in open session. That such is a move in the right direction, no one who has watched the purely political manœuvring of the last few years can deny. The measure will doubtless commend itself to every member outside of the old rings that have governed the Society for such a long period. In fact, there has been more of petty politics in this organization than in any similar one throughout the country. And this is saying a great deal, considering what we have been called upon to notice recently in connection with elections in our own local societies. Bargains have been made with the assumed leaders which would have disgraced a ward primary. This is done year after year, until even the majority of the conscientious workers in the Society has begun to believe that the cliques own the entire concern. Thus it happens that not infrequently in farming out districts men attain the highest place who are not known outside of their counties, and whose only recommendation is centred in their ability to work their constituents.

It is now time that the members should look at the situation with the proper incentive for reform. The first step to be taken is against the so called and self-constituted district leaders. The Society should do its best to discourage lobby work in every form. If proper inquiry is made it can easily be ascertained that the men who claim the right to dictate for their districts are not really the ones who could do so when at home. It is simply because they have more leisure and taste for such work than the quieter members, who are too busy with their purely professional work to give the matter the attention which it otherwise merits.

We wish in this appeal to prepare the Society for a proper consideration of the proposed change in its management. Its adoption is not only a reasonable measure, but is fraught with the greatest good to the Society as a whole. It is a commencement in the right direction, but let it be made at once, so that other necessary reforms hinging upon it may also be in time consummated. There certainly can be no objection to making a nomination in open session. It might surprise the ring, but it would gratify the majority, which would naturally vote for the best man—the one who had fairly won the right to such an honored position. We would not then be compelled to inquire after the officer is elected, Who is he? What has he done? and Why was he chosen?

SANITARY MOTES AND BEAMS.

UNDER this suggestive title the Medical Director of the Navy, Dr. A. L. Gihon, has published in the November issue of the *Sanitarian* an interesting account of the present status of sanitary affairs in our country. While much has been accomplished, he holds that much more remains to be done. He believes that the ascendancy of hygiene has greatened and glorified medicine, without dimming the lustre of any other branch; but though her cult is established, her mission has not ended with the recognition of her supremacy and the faithful following of her own ilk. To-day she turns to the people and their rulers, outside the medical fold, and demands the place in their councils that is hers of right. A makeshift share in the administration of the sanitary interests of the country has been grudgingly allowed, but the inexorable demands of modern enlightenment cannot be satisfied until the conservator of the public health shall sit a peer among the rulers. He is emphatically of the opinion that the interests of the public health must be intrusted to a department of the Government especially charged with their administration, with equal independent execu-

tive authority as given to other national departments. Temporizing legislation under the spur of emergencies does not befit this age. As the enlightened physician seeks to prevent his charges becoming ill, so should the guardian of the public health be able to forestall these emergencies, whose pecuniary cost, in money expended and wasted, in trade paralyzed and diverted, in labor and its wages lost by the sick and terrified and dead, in a single epidemic, exceeds that of maintaining an efficient sanitary service for the whole country for a whole year. He thinks that the fault of the medical profession has always been its lack of bold assertion of its rights; but it can no longer hesitate to declare to trade and commerce and agriculture and manufacture that the health and vigor which are essential to prosperity cannot be secured by their own unskilled, uninformed efforts. They must learn, as the military services have learned, that powerful armies and navies are the results of able and untrammelled medical departments. It is as unwise to confide the care of the national health to a financier, however astute, as to expect a postmaster-general to understandingly control a bureau of agriculture, or a fishery commissioner to best administer the affairs of the public schools, or an attorney-general to direct the mining industries. The health of a nation is a national consideration involving international co-operation. There should be no priority nor clash of sectional interests. State lines are not respected by epidemic intruders. No State barrier can be so defensive and impenetrable that the toxiferous germ cannot pass through.

The readers of the RECORD know that it has repeatedly urged the establishment of a bureau of this kind. At the present session of Congress our legislators should be compelled to take action looking to the creation of a Department of Public Health. The depleted condition of the national treasury should not be accepted as a valid excuse for postponing the necessary enactments.

Dr. Gihon next takes up the discovery of motes abroad when the beams at home should first receive consideration. The scientific tendency of the day is literally toward mote-hunting through microscopes, instead of using our human eyes upon visible abominations. The sanitarian, official or amateur, need only look about him to be appalled at the spectacle of indifference of rich and poor, high and low, to dangers far greater than any from cholera microbes, which confront them every hour, and it may be worth our while to indicate some of these beams in our own eyes, which we complacently refuse to see, while we magnify the motes on our horizon. The various forms of civic filth here come in for their share of just condemnation.

The author forcibly points out that the preventable disease which kills more of the human race than cholera and yellow fever together, and in its ordinarily slow process of killing lessens the productive power of a community directly by the enfeeblement of its victims, and indirectly by its demands upon members of households and eleemosynary institutions for the care of these chronic invalids—tuberculosis—is tolerated with as little concern as the Mongolian exhibits for small-pox, or the creole for yellow fever and malaria. The consumptive, whose traits no professional acumen is required to recognize, frequents our crowded thoroughfares, sits beside us in unventilated street cars and at the hotel table, occupies Pullman sleeping-berths, and shares the steamship state room, wholly unrestrained and innocently ignorant that he or she may be sowing the seeds of disease among delicate women and children. Anyone may verify this who uses his eyes for the purpose along the railway and coastwise steamer routes to our invalid resorts.

In regard to filthy cellars, he properly observes that no city can be accounted clean until its ordinances require every cellar door to be widely opened to sun and air—that royal pair of germicides; every cellar to be emptied of its refuse; every cellar wall and ceiling to be scraped and whitewashed; every cellar floor to be taken up if rotted, and sprinkled with lime if uncovered—a tedious and expensive process; but effective sanitation, costly as it must need be, is cheap beside the outlay of a single epidemic. There are underground foulnesses in all our great cities of which they should be rid at any cost, as where rag-pickers and bone-gatherers collect their filthy stores, and Italian street-corner fruit-sellers keep their decomposing bananas, grapes, and oranges, till, rubbed off by dirty pocket-handkerchiefs, they are exposed for sale, glistening after their repulsive polish with impure saliva.

According to Dr. Gihon, the sanitary inspector is destined to become the most important agent of future civic administration. The perfunctory burning of a pan of sulphur in a diphtheritic chamber, the sprinkling here and there of a solution of corrosive sublimate, or the substitution of the sweeter scent of thymol, pinol, or some newer "ol" for the foul odor of the privy, will not then be the tolerated limit of his interference. All that science teaches and all that intelligence can devise will be exacted of him. A sanitary inspection will be a deliberate, painstaking, critical examination of nooks and corners and their disinfection, the flooding of the lairs of microscopic motes, and the deluging of unsightly beams with those unstoppled, unpatented, inexhaustible germicides—air and sunshine.

The writer also puts himself on record as opposed to indiscriminate immigration, in the following language: The great caldron in which we are mixing Celts and Saxons, Semites and Aryans, with a seasoning of syphilis, tuberculosis, and insanity, is simmering with what ultimate homogeneity can only be conjectured. When immigration was a tiny stream, however muddy and noisome, poured into a rapid river of pure water, it was soon lost in the crystal fluid; but now that huge sewers are discharging their fetid pestilential torrents into a placid lake that has no outlet, the lake itself becomes turbid and unclean. Already in the *culs-de sac* which are nearest the open mouths of these foul sewers and receive their floating scum—the prisons, reformatories, almshouses, insane asylums, and hospitals—this filthy, debased, and diseased foreign element is ascendant, and our demographers have a simple task in representing its volume by numerical statistics. Dr. Frederick H. Wines, the distinguished compiler of this portion of the census of the United States for 1890, demonstrates by the indisputable evidence of figures that, while the foreign-born constitute only seventeen per cent. of our total white population—in round numbers about one-sixth—yet they furnish over half of all the paupers in the almshouses of the country.

That Dr. Gihon has not made random assertions and

has not used colors of too sombre a hue for his pictures, can be easily ascertained by a study of facts and figures. But perhaps Congress needs the "object lesson" of actual disaster before giving sanction to any system of broad national prophylaxis, such as might come within the scope of a Bureau of Public Health.

SIZE AND QUALITY.

One of our esteemed contemporaries, the *Journal of the American Medical Association*, gives a wrong impression of its relative size by stating that it publishes in its last volume one hundred and sixty-four more pages than the Medical Record. But as there are nearly one hundred and fifty more words to a page on the Medical Record this is not a fair presentation of the matter. We have, however, always insisted that quality is better than quantity. As against the argument of mass we should be content to contend that the original articles in the Medical Record were never more original and helpful, the editorials never richer in practical interest, never more scientifically sound, syntactically correct, rhetorically resourceful, or more keenly alive to the intellectual comfort, moral aspirations, and multitudinous practical needs of its readers. Nothing occurs in the scientific world which is not brought promptly to their attention; and no question of political or economic interest which agitates any portion of this Union fails to receive proper and considerate treatment. The troublous times in Texas, the aggressive progress of Cook County, the high fees and mild temperature of the Pacific coast, the alert organization spirit of the Northwest, the struggle with commercialism in the South, the recrudescence of activity in the decadent towns of New England, the phonetic spelling of Philadelphia, the halo around Johns Hopkins, the buttons of Dr. Murphy, and the passing of Mr. Hart, all have received at our hands the consideration which their contemporaneous interest deserves. So we venture to say again that it is quality and not quantity which makes success. And we are sure that our readers will forgive the foregoing modest encomium upon ourselves, since its purpose is impersonal and general, and intended only to illustrate a great and fundamental truth.

THE STAR-SYSTEM IN MEDICAL EDUCATION.

Under this heading the *Medical News* advocates sweeping reforms in the conduct of medical faculties. Our contemporary believes that the organized and vivified medical college is to take the place of the cluster of individual medical star-professors of the past—that personalities are to be subordinated to a system, leading rôles to be merged into a harmonious unity, men into an institution. A great work is to be done, a work requiring a large number of specialized workers, each performing his peculiar function, each the equal of the other, and all running to a unity of result that leaves no place for exaggerating one or two rôles, while extinguishing all others. It is clear, therefore, that the college which soonest and best meets the new ideal will be the college of the future, and the college that clings to the methods of the past, seeking a few leading actors and cruelly silencing subordinates—with necessarily resulting jealousies and self-seekings—must assuredly go down. Such a college as this last inevitably becomes ring-ruled, the financial aspect ever uppermost, never willingly lengthening the course or raising the entrance standard.

The *News* has also discovered that the star-system of medical instruction and the monopoly it engenders seems to be arousing the indignation of our colleagues over-sea. From the recent noteworthy inaugural address of Professor Black, of Glasgow, a few paragraphs are quoted:

"If there be one thing on earth which should be as free as the winds of heaven, it is the right to impart knowledge, no less than the inalienable right, if a man feels so inclined, to make that knowledge a marketable commodity. Nothing is more tenacious of life, nothing dies harder, than a corrupt and profitable monopoly. It is surely superfluous to argue at this time of the world's history, that it should matter little to an intelligent or a discriminating public where or from whom a man receives his knowledge, providing he gives satisfactory evidence of the possession of it. It requires no argument to demonstrate that monopolies of every kind are subversive to the best and highest interests of the people, and that of all monopolies, monopolies of learning are the most wicked and the most indefensible.

"If the laborers are numerous, then we have the usual effects of competition—industry, dexterity, and moderate wages. If, on the contrary, the laborers are few in number, then we have, as usual, carelessness, bad work, insolence, and exorbitant demands."

The *News* concludes its trenchant attack on our medical colleges and the old-time professors as follows:

"This new tendency, nay, this coming and pressing necessity, does not in the least extinguish individuality, but leads to its healthy development. It was the old plan that with ruthless barbarity throttled all individuality except the egregiously selfish individuality of the star, and that smothered nascent ambition and possible teaching ability in order not to permit rivalry. The new plan, with its enormous increase in numbers of the teaching body of a college, encourages the healthy growth of individuality and of special ability. But it does one other most important thing: it reduces to useful subordination all egotistic advertisers and self seekers, and binds individualities together for a work and a system that outlasts and is of more importance than individuals."

The *News* is evidently on the war-path, and we wish it success in its campaign of reformation. There is no doubt that too many medical men become "professors" from purely selfish motives, such as building up a consultation practice, or posing as "eminent authorities" before the laity. On the other hand, unless "professorships" are made attractive and profitable, the best talent will not be eager to enter the charmed circle of professorial dignity. Human nature is not materially altered by the possession of a medical diploma. Unless professorships "bring in" something tangible, only mediocrity will stampede toward the empty honors of the college chair. Good men demand good rewards in this matter-of-fact world. Emoluments are just as attractive to doctors as they are to lawyers, or to clergymen, or to plain every-day business men. The professor of the future may not care about sordid details of compensation for his work. But we take it that that kind of professor is a dim and nebulous hypothesis, whose chair is not planted

on terra firma. A flesh and blood professor needs his three meals a day, just like ordinary mortals. And we believe, in most instances, he deserves them. If they really need more professors over there in Philadelphia, we might, on a pinch, let them have a few of our own. A famine of professors is not what we are seriously threatened with at present in New York.

News of the Week.

An Army Medical Examining Board will be in session at Washington City, D. C., during April, 1894, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before March 15, 1894, for the necessary invitation, giving the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from which they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates, based on personal acquaintance, from at least two reputable persons, as to his citizenship, character, and habits. The candidate must be between twenty-two and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the Board. Successful candidates at the coming examination will be given a course of instruction at the next session of the Army Medical School, beginning in November, 1894. Further information regarding the examinations may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

A Four Years' Course at Jefferson Medical College.—At a meeting of the Faculty of Jefferson Medical College, held on January 8, 1894, it was unanimously resolved to institute a compulsory four years' course with the session of 1895–96. This step was taken in order that the large clinical service of the Jefferson College Hospital (350 cases a day) might be utilized to the fullest extent in carrying out the desire of the Faculty to provide advanced medical education of a practical character.

The New York Ophthalmological Society.—At the annual meeting, held on Monday, January 8th, the following officers were elected: *President*, Dr. W. S. Dennett; *Vice-President*, Dr. Frank N. Lewis; *Secretary and Treasurer*, Dr. D. W. Hunter; *Committee on Admissions*, Dr. Henry D. Noyes, Dr. Arthur Mathewson, and Dr. J. B. Emerson.

The Lunacy State Care Act.—The report of the Board of Trustees of the St. Lawrence State Hospital has been printed and transmitted to the Legislature. In this report the State Commission on Lunacy is criticised for its construction of the lunacy laws. The trustees say:

"The Board desires to record itself again in favor of such central supervision of the management of the State hospitals as shall place salutary checks upon extravagant expenditures or other abuses of administration, as we understand the Legislature intended by powers conferred upon the State Commission in Lunacy, but we most earnestly protest against the assumption of powers on the part of the Commission which denies, or renders nugatory, authority given by statute to managers and resident officers. We believe the Legislature never intended to supersede the local authority, but instead aimed to create a wise and proper supervision of the hospitals by a central co-ordinate body; nor does the statute, to our mind, imply otherwise, though a different construction is being enforced by indirection and advantage of situation.

"The act that went into effect upon the first day of October last has given us about three months of experience, and has been in operation for a sufficient time to show us that in the administrative functions of the hospital we have practically no power. This might not be objectionable as a personal relief, provided we were at the same time relieved of responsibility; but we cannot learn that your honorable body has relieved us by statute from the responsibility created for us in the organic law. If we are relieved of both power and responsibility, then the need of Boards of Managers does not longer exist, and they should be permitted to lapse into desuetude or be wiped out altogether.

"The question that now presents itself more plainly than ever before in the history of this State, is whether the interests of the State, as well as the interests of the insane committed to its guardianship, will be better served by a Central Board with absolute power, over which there can be no supervisory or controlling body except that of the Legislature, or by a divided responsibility in the several local Boards of Managers, as heretofore, with a central supervisory body having ample power to correct abuses, either by appeal to the Executive, the Legislature, or the courts. It must appear self-evident that a better service can be maintained under the latter system than under the former. We cannot believe it is your intention to set us aside, and elevate a service that imputes to us, as to all local Boards of Managers, neglect of and incompetence for our responsibilities."

Death of Dr. Herbert Judd, of Galesburg, Ill.—Dr. Herbert Judd died suddenly from apoplexy, at his home, January 11th, aged fifty years. He graduated at the Albany Medical College in 1867, after which he settled in Galesburg, Ill., where he practised until his death. For a long time he was surgeon of the Chicago, Burlington & Quincy Railroad, and for several years previous to his death was surgeon of the Chicago, Santa Fé & California Railroad. He was a leading spirit in his community, and was in every way the type of a successful physician.

Alumni Association of the Woman's Hospital of the State of New York.—Dr. W. Gill Wylie gave a reception to the Association on Tuesday evening, January 16th. There was a large attendance of members and outside friends.

Eleventh International Medical Congress.—A letter directed to the undersigned by the Secretary-General of the Eleventh International Medical Congress, and dated December 19, 1893, contains the following communications: "American members will pay on the English, French, and Italian railways single fares for double journeys, and will obtain a reduction of twenty per cent. on fares for Italian round-trip tickets. The documents required for their identification will be sent to you in January, and Americans intending to visit the Congress

will have to apply to you for them. Full particulars concerning the journeys will accompany the documents. Messrs. Thomas Cook & Son, London, Paris, Rome, and Naples, should be applied to for accommodation and for tickets for the excursions at Rome, Naples, and to Sicily. Such excursions will be arranged at Rome under the guidance of Mr. Forbes, member of several scientific societies and correspondent of the *Times*—for Naples, three days, including Vesuvius, Pompeii, Capri, Sorrento, Castellamare, Bajae, etc.—for Sicily, ten days from Naples, including Messina, Taormina, Catania, Girgenti, Siracusa, Palermo, and return to Naples. The fares for members of the Congress will be considerably reduced, and comprise hotel accommodations, carriages, guides, boats, etc.—about 70 francs each, for the three days, and 285 francs for the ten days. Full particulars concerning these excursions will be contained in a leaflet to be added to the instructions and documents for the journey."

From former communications the following are herewith quoted: "The members' fee is five dollars, that of their wives or adult relations two dollars each. Checks or money orders may be sent to Professor L. Pagliani, Rome, Italy. Credentials have been promised in the near future. When they arrive (none were received last year), they may be too late for many who have started or are about to start. The undersigned, who is not informed of the cause of delay, proposes to supply in as official a form as he thinks he is justified in doing, credentials which are expected to be of some practical value. The North German Lloyd has promised to recognize them. It is suggested, besides, that a passport may increase the traveller's facilities. Only the North German Lloyd (22 Bowling Green) and the Compagnie Générale Transatlantique (3 Bowling Green) have thought fit to grant any reductions to Congressists. The reductions on Italian railways are available from March 1st to April 30th.—A. Jacobi, M.D."

Death of Dr. S. Guttmann.—Dr. S. Guttmann, editor of the *Deutsche Medicinische Wochenschrift*, died on December 21, 1893, in Berlin, of severe influenza with pneumonia. One of the busiest and best-known men in medical circles, his death will be widely regretted. Under his able editorship the above-mentioned journal has become one of the most widely read of German medical papers.

To Abolish the Office of Coroner.—The following is an abstract of recommendations contained in the memorial of the select committee of the Medico-Legal Society of New York, addressed to the Legislature of the State: Your memorialists after duly considering the premises unanimously recommend to your honorable body: That you amend the existing statutes, regulating the powers, duties, and compensation of coroners. (*a*) By creating a new officer to be styled "Medical Examiner," as in Massachusetts and Connecticut, or "County Physician," as in New Jersey, who shall be authorized to conduct inquests or examinations in all cases where death has occurred by violence, or there is reason to suspect that the same is due to other than natural causes, having charge of all autopsies and all questions on the medical side of the inquiry, without a jury before a competent court, or before the coroner as a judicial officer, if retained after the plan adopted in Connecticut. (*b*) That said medical examiner be appointed by the county judges of each county, except New York, and by the Chief Justice of the Court of Common Pleas in that county, and only physicians skilled in their profession, of at least five years' practice, to be eligible to such appointment, and so far as possible without reference to partisan political considerations. (*c*) That only persons learned in the law shall be eligible to the office of coroner, and that if the inquiry is conducted before the coroner, he shall have charge judicially of all legal questions, and that the hearing, inquest, and proceedings shall be the same as if before the Police Magistrate in the City of New York or other cities of over 100,000 inhabitants, and before justices of the peace in all counties of the State except New York and Kings Counties.

And your Memoralists will ever pray,

Clark Bell, *Chairman*, Theodore H. Tyndale,
Charles G. Garrison, Wyatt Johnson, M.D.,
Abram H. Bailey, H. W. Mitchell, M.D.,
Moritz Ellinger.

Dated January 10, 1894.

New York County Medical Association.—The annual meeting of this Association took place January 15th, and the following gentlemen were elected to office: *President*, Dr. S. B. W. McLeod; *Vice President*, Dr. Augustus D. Ruggles; *Recording Secretary*, Dr. P. B. Porter; *Corresponding and Statistical Secretary*, Dr. W. W. Van Arsdale; *Treasurer*, Dr. John H. Hinton; and Dr. J. Blake White, member of Executive Committee. There had been but one nominee for each office except that of President and Executive Committee.

To Investigate the State Commissions.—Senator Mullin has introduced a resolution providing for an investigation by a committee of the Senate of all the State Commissions, with a view of consolidating some of them if the information secured justifies it. This will give an opportunity for the Lunacy Commission to prove its right to exist in its present shape. Consolidation would easily solve difficulties connected with real economy in the administration of the State Care Act.

Small-pox in Charity Hospital.—Three patients in the Charity Hospital, on Blackwell's Island, developed small-pox January 16th. All were taken to Riverside Hospital. They caught the disease from a man named Schmidt, who died in the Charity Hospital last week. Schmidt's body was taken to Bellevue for dissection, and it was not until then that the discovery was made that he had died of small-pox. A diagnosis was not made at the Charity Hospital. The patient was in the hospital at least a week, and exposed many persons to the disease. The attendants and the patients in the ward in which Schmidt was have been vaccinated, and the ward fumigated. Four more cases of small-pox occurring in Harlem were reported the same date. They were sent to North Brothers' Island.

The Cincinnati Academy of Medicine in New Quarters.—The evening of January 8th was a jubilee occasion in this veteran organization. It was the inauguration of an entrance to larger accommodations, and upon a higher and greater degree of usefulness. It was a genuine field night, where there was a feast of reason and flow of soul. More than three hundred members of the medical profession were present, nearly all of whom were members.

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, December 18, 1893.

S. B. W. McLeod, M.D., President, in the Chair.

The Chief Factors in the Production of the Diseases Peculiar to Women.—Dr. T. Gaillard Thomas sent a paper on the above subject, which was read by his associate, Dr. Carmalt. (See p. 65.)

The Curse of Gonorrhœa.—Dr. George T. Harrison being of the impression that gonorrhœa had not been mentioned in the paper as an etiological factor in the diseases peculiar to women, spoke of it as one of the most common and potent factors. Noeggerath's position, taken many years ago, had been fully vindicated. The dangers to the wife of latent gonorrhœa in the husband were great. It was more dangerous to a woman for her husband to have gonorrhœa than syphilis. He had some faith in the microscopic examination of the chronic urethral discharge, in spite of the views held by Taylor, Sturgis, and others. A sad instance was related of marriage of an attractive young lady of nineteen, to a widower of thirty-five, followed by backache, prolonged menstruation, pelvic pain, fever, metrorrhagia, endometritis, salpingitis, oöphoritis, peri-oöphoritis, then contraction (by accident, of course) of gonorrhœal ophthalmia and loss of one eye. How often did we see young women entering upon marriage have their bright hopes for offspring blasted by a latent gonorrhœa in the husband. Almost constant results of gonorrhœa in women were ill-health, sterility, and hysteria.

Unnecessary Gynecological Interference.—Dr. H. J. Boldt thought more stress might be laid upon faulty dress and hygiene in the production of diseases peculiar to women. High heels were not a little to blame for pelvic troubles, which they induced by throwing the pelvis into an abnormal position. Gonorrhœa was an important factor, it was true, but he believed it had been over estimated. More pelvic disease came from abortion than from gonorrhœa. It was the chronic, not the acute, form of gonorrhœa which produced dire results in women. Another important factor was unnecessary gynecological interference. Men put in pessaries where there was no indication for them, and resorted to procedures which set up inflammation in the uterus and its appendages which had not existed there before, or not in acute form. The sound was introduced, or simple operations performed without such preparation as was called for by major operations, and the result was septic inflammation. The semen of the husband should always be examined where women applied for treatment because of sterility.

Neglected Dysmenorrhœa Prior to Marriage.—Dr. A. H. Goelet wished to call attention to the influence of neglected dysmenorrhœa prior to marriage in the production of suffering subsequent to that event. Although one of the most common factors in the production of uterine disease, it was frequently overlooked. The physician was not always to blame, for sometimes an examination of the unmarried woman was denied, although urgently indicated. In unmarried women with fibroid tumors he had never failed to get a history of early dysmenorrhœa. Neglect of the bowels was another frequent cause of female diseases. Still another very important factor consisted in imprudence during menstruation. Obliquity of the pelvis caused by abnormal positions of the body was another cause, and might be due to occupation and dress. Dirty operations were another cause. Every operative procedure, however simple, called for the degree of neatness observed on entering the peritoneum.

Imperfect Pelvic Organs in Well-developed Women.—Dr. Tull had seen three cases within two years in which there was quite or almost complete absence of the uterus and ovaries in women otherwise well developed, and who had lived in a manner supposed to favor development of the pelvic organs. In some cases at least, the care of the child had nothing to do with imperfect pelvic organs and diseases arising therefrom. In some patients he had elicited a history of scarlet fever at or before puberty. In one case he had found gummata of the ovary, showing that syphilis might affect those organs as well as others. He believed gonorrhœa to be the most potent cause of pelvic inflammations, yet it was difficult to prove this by comparative statistics, for the reason that so few husbands had not had gonorrhœa. Want of cleanliness on the part of women was, he believed, one of the most prolific sources of trouble. He had repeatedly seen fever and symptoms of mild septicæmia disappear after thorough cleansing of the vagina, showing that there had been absorption of retained secretions.

Dr. Boldt inquired of Dr. Tull whether he advised vaginal douche immediately after labor.

Dr. Tull said no, but he advised it after the third or fourth day, simply for cleanliness. He believed vaginal douches should be given a great many women who had never borne children.

Dr. Harrison warmly opposed the use of douches immediately after labor. The vaginal canal and uterine canal may be regarded as aseptic after normal labor. He had, indeed, performed numerous operations, resorting to the forceps, version, etc., and had not met with sepsis although douches were not employed. But he observed antisepsis with regard to instruments and hands. Dr. Harrison also combated the suggestion that uterine retroversion was unimportant. It was always abnormal.

Some further remarks were made with regard to douches, and Dr. Robert A. Murray gave the results of methods practised at the Maternity Hospital, where they had reduced the mortality and sepsis to as low a point as in any maternity hospital in the world. During the three years from 1890 they had had 957 confinements, with about 110 forceps operations, 28 versions, 8 craniotomies, 1 Cæsarean section, 2 symphyseotomies, and only one case of sepsis out of the 957 confinements. All the doctors connected with the institution had pursued the same course of treatment, which was to secure asepsis. This, however, was only possible through antisepsis. The douche was not used after ordinary labors.

Dr. Murray thought the reason why so many women suffered after abortion, was the fact that they regarded it as a trivial matter and exposed themselves afterward. In unmarried women one of the most common causes of disease was lack of care during the menstrual period. They went out in light shoes, remained up late, dressed so as to force all the organs down on the pelvis. In consequence, inflammatory states arose which were the foundation for numerous other diseases.

The President made a few remarks, and spoke of the great reduction of puerperal fever as evidence of the interest shown by the medical profession in the health of the gentler sex.

After the presentation of an instrument and some pathological specimens, the Society went into executive session and made the following nominations: For *President*, Drs. McLeod, Harrison, and Valentine; for *Vice-President*, Dr. Ruggles; for *Secretary*, Dr. Porter; for *Corresponding Secretary*, Dr. Van Arsdale; for *Treasurer*, Dr. Hinton. Member of Executive Committee, one to be elected, Drs. A. H. Goelet, J. Blake White, and Edward von Donhoven.

Lupus.—Harrison counsels the following procedure: On retiring at night the patient covers the diseased part with a compress dipped in an eight per cent. aqueous solution of sodium hyposulphite. On waking, the compress is removed and topical treatment made to the lupus nodules of hydrochloric acid, five drops in thirty grammes of distilled water. This is continued over eight days. The crusts fall off, leaving ulcerated surfaces which cicatrize rapidly under the use of zinc oxide or boric acid.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, December 19, 1893.

CHARLES E. QUIMBY, M.D., CHAIRMAN.

Specific and Relative Value of the Important Factors of Longevity.—In arranging the discussion on this subject, the Chairman had requested examiners for several of the life insurance companies as well as others to take part. He first called upon DR. E. W. LAMBERT, who said he responded to the invitation with some diffidence because he found the subject so complex, the factors so many and apparently contradictory. Of course, in his long experience as examiner for life insurance, the question of longevity had naturally presented itself. In spite of the long time this question had been before him, he could not say that it had particularly cleared up; it was still debatable as to what were absolutely important and also relatively important factors of longevity in individual cases. In the first place, however, we must exclude two words, viz., always and never.

Long-lived Ancestry.—The first important factor, it seemed to him, was that the man should have a good inheritance. No one could deny that long life on the part of ancestry on both sides of the house was an important factor in considering the longevity of the individual. Indeed, he knew of no other single factor of as great importance, yet one might feel staggered at times to meet with a case in which a mixture of the blood of a long-lived couple resulted in a short lived progeny. This was the exception and due to peculiar combination.

Environment.—The next question of importance was that of environments, or the conditions in which a man was born. A comfortable, well protected, well-organized household, and sanitary surroundings were pretty sure to carry the child through early life with all its attending accidents.

Temperament.—The next important factor was temperament. It seemed to Dr. Lambert that a placid, calm, philosophical way of looking at things was much more conducive to longevity than the irritable, fretting, fussy, fault-finding way observed in some people. This was well illustrated in the case of animals. In a span of horses going up Fifth Avenue it would be observed often that one horse would go quietly along and do all the pulling while his mate danced, pranced, and cavorted around, wasting his energy and shortening his life with little good.

Manner of Living.—The next matter of importance, he thought, was the way of living. The man who was careful, considerate, and moderate in the exercise of all his faculties, whether animal or intellectual, was one who would last longer than the man who over-indulged in any one of the numerous things which go to make up life. The men who broke down and died prematurely were usually those who had not lived temperately. It was often said that men worked themselves to death, yet the more he observed people, the more did he become convinced of the correctness of the Western editor's assertion that men do not die of overwork, but rather of what they take between work. He thought it would be found that what killed men was not work, but what they did outside of their work; yet he did not believe in total abstinence in any sense. There was no law, with regard to eating and drinking and manner of living, which could be laid down as applicable to all individuals. Each person must find out the law which applied to himself and obey it. Each person could usually discover what agreed and what disagreed with him, and if longevity was sought after he would have to avoid the things which evidently disagreed with him and seek the things which did agree with him.

Exceptions.—Dr. Lambert added that he was aware that to what he had said one could bring exceptions by the thousand. Take any one of the factors which had been mentioned, and one could mention men who had lived long without any; for instance, with regard to alcohol, men could be found who had done nothing much but drink all their lives, and yet had lived to a full age; but when one found a man who had drank hard all his life, he could be pretty sure he had done nothing else.

All were subjected to circumstances which they could not altogether control, and at times found themselves compelled to do things which they were advised not to do; and now and then it happened that even then, in the case of the person who seemed to possess all the factors of longevity, death ensued early in life.

Professional Athletes Short-lived.—DR. BRANDRETH SYMONDS said that when he was asked to take part in the discussion he expressed the opinion that the subject was rather a large one, whereupon the Chairman had kindly extended him the privilege of nibbling at it here and there. With regard to the effects of athletics upon the expectation of long life, it was notorious that professional athletes were short-lived. In seeking a reason for this he had had opportunity to examine four, and only one of the four showed no abnormality. The others had cardiac hypertrophy, one a little emphysema, one a trace of albumin and sugar in the urine. It was different with amateurs, for they left the field before permanent lesions developed. He had examined eleven good amateurs with reference to the question whether they were desirable subjects to insure, and he had found all but one practically sound. The one who constituted the exception had a narrow chest, thirty inches, and secondary enlargement of the heart as a consequence.

The Influence of Build.—DR. OSCAR H. ROGERS thought Dr. Lambert was quite correct in regarding the family history as the most important factor in longevity. In the exceptional cases where longevity in the parents had not been transmitted to the offspring it might, perhaps, be accounted for by moderate extremes in some respects existing in both parents, combining and causing marked extremes in the offspring. The form of body was, he thought, next in importance to family history. A person might not only be too heavy, but his fat might also be accumulated in the abdomen instead of being evenly distributed.

About Consumption.—Dr. Rogers had once considered the question, what persons might be expected to die of consumption, and on looking through a life insurance list had found that about one-fifth of those dying of consumption gave a family history of that disease. Stated in a different form, about four-fifths of the people who died of consumption in adult life gave no history of this disease in their immediate family. Approximately, seven-tenths of those who had died of consumption were under average weight and build. Very few were of the average weight, and fewer still above it. Gout was of sufficient frequency in England to be considered in the family history by insurance companies, but in this country neither it nor rheumatism were considered of so great importance. After the question of disease in the family and the points previously mentioned, he next laid most stress upon habit. Some persons would train well on five-pound dumb-bells, others better on ten-pound ones, and it was the same with alcohol: one man would be a raving maniac with a single glass of alcoholic drink a day, of which another man might take half a dozen glasses and live to eighty or ninety years. He would, therefore, like to see a little wider latitude given the individual—not every individual—in the use of alcohol.

Dr. Rogers had looked over a list of five thousand deaths, in persons whose lives had been insured, with regard to the cause, and had found that about twenty-five per cent. had died of diseases of the lungs, and about ten per cent. of these had died of tuberculosis, probably ten per cent. of pneumonia, the other five per cent. of bronchitis and other affections of the lungs.

Dr. Rogers also said, in passing, that post-graduate instruction in New York and other centres had decidedly raised the standard of rural medical men who made preliminary examinations of those applying for life insurance.

The Mutual Influence of the Different Factors in Longevity.—The Chairman asked some questions regarding how far inherited constitution might be modified by environment, the mutual influence of the several factors relating to longevity, and the propriety of considering them in granting life insurance.

In reply Dr. Lambert said he had not gone into details, as it would have required all night. With regard to weight, there were two sources of danger, one in light weight, and a very different one in heavy weight. Light weights, as a rule, developed their diseases before forty, heavy weights after fifty. The rule applied in the selection of recruits for the army was the safest he knew with regard to relative weight and height. One was taking an extra risk in insuring a man who did not weigh two pounds to the inch in height. For instance, if a man measured five feet ten and weighed less than one hundred and forty pounds, his life was an extra risk. Of course, there were marked exceptions to this rule. In the same line, if a man's chest did not measure half his height, the risk was great. If both the weight and chest measurement were below the proper proportion compared with the height, the sooner the case was barred out the better for the insurance company.

His idea with regard to fat men was, that the danger increased in proportion to the size of the belly. He did not regard a stout man as an extra risk if he came of a good family and his flesh was well distributed. But if a man's chest measured 36 and his belly 46 inches, he was more likely to die of fatty degeneration than if the chest measured 38 inches. Such persons usually died of diseases "below the belt." The farther a man was away from the ordinary standard in build, the more critically did he inquire into the family history, his personal habits, whether he took more nourishment than any decent man could burn up, and so on. The difficulty with high living was that a man put nourishment into his stomach faster than his excretory organs could eliminate it. He put into his furnace so much coal that clinkers were sure to form, and he would die of some one of the results of carrying in his blood a lot of stuff which ought to be excreted.

The Danger from Alcohol.—Dr. Lambert thought the danger from alcohol lay less in the alcohol itself than in the fact that the subject was apt to keep his stomach on the grind from morning till night, giving it no time, much less half the time, in which to rest.

Bodily and Head Measurements and other Factors.—Dr. M. Morris continued the discussion with a paper. He had studied the subject of longevity more or less for a good many years, not alone in connection with life insurance, but also as a general practitioner should do. Inherited tendency to longevity was an important factor in treating disease. Persons inheriting short life did not present as good prognosis in disease as those inheriting long life. This was especially true in critical diseases. There was an indefinable something in the human organism, varying in degree and force, termed tenacity of life or natural resistance to disease, by which some persons passed most successfully through serious maladies and injuries, while others without so much natural resistance succumbed. This was every-day experience, especially in surgery. This statement did not, of course, imply that proper treatment had not much to do with the successful result.

In a large proportion of those endowed with tenacity of life the ancestry would also be found long lived. Like in other living organisms, some parts of man's system decayed and perished before others. The vital principle was seen to carry on its active process in one organ and another until each one in turn faded, and the being was unable longer to maintain life. It was not within human ken to describe this vital principle, but by observation it was known that certain conditions would cut it short, yet that it was impossible to prolong it by any means whatever beyond the natural inheritance. Some men were at best endowed with short life, while others, if they obeyed the law, could live a long life.

Is it Possible to Predict the Probable Duration of One's Life?—Having put this question, Dr. Morris said that inherited tendencies, habits of living, occupation, observance of sanitary laws, and residence, all had a direct bearing on the question of probable longevity. Acute diseases, bad habits, excessive indulgences, unfavorable residence, all had a life-shortening influence. In all forms of life we must find some substance in common in which life inhered and upon which life must depend. In plant life there were structures not found in animal life, and in animal life there were substances not found in plant life, but in all forms of life there was a secretory tissue. This was the only substance common to all living things. This also had its life-time, and when it ceased to exist life became extinct. This secretory tissue was the only kind of substance which was transmitted from the ancestors, and therefore it contained in itself all the ancestral influences which were transmitted But there were different kinds of secretory tissue and different proportions of each, so that the duration of life was a variable quantity. The different organs of the body were not a unit, but aggregations, and one might die and end the individual's life while others might have lived on to an advanced age. Yet a short-lived organ might not be essential to general life. A life was always a combination of inherited influences, some one of which might be of a kind to reduce the general inheritance below that of the ancestral stock. Current conditions seldom produced a better result than fairly belonged originally to the individual.

It was not unusual to remark that a person inherited red hair from the mother, or a dark complexion from the father, and so on. Why, then, not inherit the stomach from one parent, the liver from the other, and similarly with other organs? One brother resembled in outward appearance almost entirely the mother, a sister the father; if so without, why not within? A great-grandfather died of heart disease at seventy-six, a grandfather at seventy-one, a father at sixty five. A son resembling this father might rightfully infer that he would die still younger of the same disease. But instead of calling it disease, call it the natural life shortened by a weakness in the paternal ancestry. Like caused like.

Can the Constitutional Inheritance or Life-time of Organs be Discovered by External Appearances?—To this question Dr. Morris answered certainly, in the majority of cases. In the first place, by studying the physiological relations of the organs of the body and their mutual influences; second, by observing the external manifestations; also by family history of longevity. A person whose ancestors were long-lived on both sides would, as a rule, be both healthy and long-lived, and able to endure much hardship and grave maladies On the other hand, those who inherited short life could not by any prescribed system of living protract their short life inheritance. General average law did not form a basis for estimating individual longevity. Lucas had stated that the average life depended upon locality, hygiene, and civilization. But individual longevity was entirely exempt from these conditions. Everything tended to show that long life was the result of the initial principle of vitality which privileged individuals had received at their birth, and this was so deeply imprinted in their nature as to make itself apparent in every part of their organism. It was not the habit of the man who was excitable and always in a hurry, which made his life a greater risk than that of a calm, philosophical person: it was rather the inherited quality which led to the difference in behavior and, in the case of the philosophical person, gave long life.

External Indications.—There were certain external indications which would give a fair idea of long and short life. It was not in one trait, but in the entire make-up of the individual who stood before the examiner. There were the color, the motions, the measurements, including size of head, which was one of the most certain indications of long or short life, for in the brain lay the

great centre of power. A person with a head whose diameter at the thin portion of the temporal bones measured five and a half to six inches was almost sure to give a longevity on the father's side of seventy to ninety years or over. If the head measured in front from the external auditory canal to the naso-frontal suture as much as four and three fourths or five inches, we might be almost sure of long life on the maternal side. A beard which was darker or redder than the hair, indicated inheritance from the paternal side; if it were lighter than the hair, the inheritance was probably from the maternal side. The length of the chest, its proportion to the circumference, to the height of the individual, and other measurements, were important.

Emphysema and Starvation.—The Chairman, DR. QUIMBY, quite agreed with Dr. Morris as to the importance of inheritance, but he had been struck with the powerful influence which habit or conditions of life had in the production of certain diseases. He referred especially to emphysema, which he said he had encountered with startling frequency in the dispensaries, and had come to the conclusion that it was due to bad food or insufficient nourishment among poor people. He had found the emphysematous chest repeatedly in persons only twenty-five years of age, or even younger, who visited dispensaries. In striking contrast with this experience, he had not in ten years examined a musician who had emphysema.

Clinical Department.

THE PHYSIOLOGICAL AND PATHOLOGICAL INFLUENCE OF VEGETABLES UPON MAN.

By MARK I. KNAPP,

MEMBER OF THE SENIOR CLASS OF THE UNIVERSITY MEDICAL COLLEGE, NEW YORK.

MAN is made up of a multitude of elements and compounds, each of them having its exact destination and each being necessary to his constitution. Each and every one of those chemicals which make up our tissues are constantly undergoing changes, are eliminated, and must consequently be supplied with new material. Must we not, therefore, be on our constant lookout to supply as well our used-up nerve-tissue as the muscular and glandular structures, fat, bone, etc.? Remembering the diversity and multiplicity of the components of the many tissues that make up our system, can we then confine ourselves to only one certain diet? Can we feed a man with only certain articles, excluding others, without a necessary reaction or disturbance taking place? Or, have all our articles of nutrition the same chemical composition which would make a selection immaterial? No, the same chemical constituents that meats have, vegetables have not; and even if they have like quality, they do not have like quantity. The albuminous matters are in different proportions in meats and in vegetables. The proportions differ in different kinds of meat and in different kinds of vegetables; and if we have enough of nitrogenous substances in a pound of meat to supply the waste of one structure, we lack the proper amount of earthy salts to satisfy other tissues. We can, therefore, neither confine ourselves to the exclusive use of meats nor to that of vegetables: they are of like importance to sustain our equilibrium of health and life.

A few analyses, taken from "Chemie der menschlichen Nahrungs und Genussmittel," by Professor Dr. J. König, of Berlin, will conduce to a better understanding.

From these analyses we see that meats, peas, beans, and some fruits are rich in albuminous substances; whereas vegetables consist of a relatively very large amount of salts, hay being very rich in calcium salts. Whereas in taking 100 gm. of albuminous matter out of the ox's meat, we would only have 5.61 gm. of salts, we should have to ingest 65.07 gm. of salts to cover the same amount of nitrogenized substance when we take cabbage, or 29.01 gm. if oats be selected as the exclusive food, or 50.256 gm. of salts if potatoes should be the nourishment. It is therefore evident that, in order to supply the necessary quantity of albuminous matter out of vegetables, we must ingest a large amount of salts. Again, to cover our lack of salts in an animal diet, we would need to take an enormous volume of it—which would be impossible for us to do. Hence by confining ourselves to an exclusively animal diet, the tissues that depend for their existence chiefly on salts will suffer; and if preference be given to vegetables, other structures will give symptoms of insufficiency in supply. It is also to be noted that sodium is prevalent in the composition of animal tissue, potassium in that of vegetables; consequently with a larger supply of animal diet, we also introduce more sodium into our system. The necessity, therefore, suggests itself to know at each period of our life, the nature, quality, and quantity of the chemical elements or compounds needed by our economy, since our system is always changing and consequently also our diet will have to vary accordingly. That menu prescribed for the developing infant or child will not hold good for the adult and *vice versa*. At the same time, finding one article to be predominantly used at a certain period of our life, we should not drive it to an excess; for any excess of one means and causes an insufficiency of the other, and consequently doing away with the necessary equilibrium, it causes insecurity, danger, *i.e.*, it hurts.

* Of which 55.65 per cent. is starch.

As a rule, we understand by the expression "nutritious food" albuminous matter; whereas it should convey to our mind the idea of such substances as are necessary to all the different tissues of our body, and certainly albumin is not the only thing that is indispensable. That nitrogenized substances are not the ideal predominable nutritious food for the infant and early childhood, that we must not overcrowd the young growing child with albuminous matter, will readily be seen from subsequent remarks.

The framework of anything is the basis of everything, and upon a sound and solid foundation the future existence, solidity, and durability of the whole building depends. However beautifully, artistically executed, the building is always in danger of breaking down if the foundation be not properly secured. It shall therefore be our duty and our first thought to secure, fortify, and strengthen also our framework. What else is our framework but our skeleton, our bones? To strengthen, insure durability, to cause developing, growing of bone in the young children, we naturally must introduce into the

system bone-forming elements, substances of which bone can be formed; and since bone consists chiefly of earthy salts, since the earthy phosphates constitute two thirds of the constituents of bone, it will be necessary to introduce into the young, growing system, such substances that are rich in salts, which substances belong not to the animal but vegetable kingdom. The same view is also expressed by König, who says: "For the growing organism earthy phosphates are of great importance, for out of these the bony skeleton is built up." This innermost, unconsciously felt desire for earthy salts and vegetables we often have occasion to observe in small children. Not unfrequently do we wonder at the perverted appetite of those little ones whom we find at times eating chalk, shells of eggs, etc. They feel and know what they want. Many children can hardly be induced to taste meat, whereas to vegetables they take readily.

The physical development of man depends upon his height and circumference, the causative factor of the first being the relative skeletal development. Of two men, short and tall, both of whom being proportionately built, the taller has a stronger and a more durable constitution; we must consequently, in order to insure strength, insure height, and to do this we must cause growing of bone by the proper vegetable diet. But since bone, like other tissues, is also always undergoing change, *i e.*, eliminates used up matter and takes up new, the necessity of not losing sight of the importance of vegetables throughout life is apparent. We also find that the ancient Roman and Greek athletes ate no meat. From all said until now, we should infer that the height of man and all animals depends upon the growing of their bones; this latter upon the proper nutrition—an assertion also expressed by Paolo Riccardi. *Only the sufficient or insufficient supply of vegetables determines the respective height of all animals and man; an abundance of vegetables which contain the earthy salts, brings forth tall, an abundance of albuminous animal diet—insufficiency of the bone-forming salts—is the cause of the non development of the skeleton, of the short people.*

Heredity and climate have been thought as probable causes of development of stature by some, who necessarily had to find an external cause for simple phenomena. Neither climate not heredity directly influence the height of man nor of animal. Nor is it the altitude. For we find tall and short men in the same village, in the same city, in the same country; we see tall people of very short parents, and *vice versa*. We meet with tall and short people in the mountainous regions, as well as in the deep valleys; tall and small men are encountered along the sea coast, as well as in the very heart of the continent. Could it be then anything else but the difference in diet that influences the growth of man and animal? Could it be anything else but the difference in the material supplied, that causes difference in appearance, quality, and durability of the machine or building produced by such material? Is it not self evident that food, and food only—that which is absolutely necessary to give to the living, life—also determines life? That with a suited nutrition growth is produced, and with a diet wanting the necessary ingredients neither growth nor long life can be sustained? Should we not look for physical and chemical causes only to explain our chemical and physical phenomena of life, instead of looking and seeking for as many causes for as many phenomena?

Of the fact that only a vegetable diet produces height of animals and man, there is sufficient proof. We only compare the two great classes of animals, the "herbivora" and "carnivora," and the most striking difference not only in height but also in other respects is at once seen. The herbivora, the older animals of our planet, are proportionately built; the carnivora, not. The height of the herbivora corresponds to the length of their body; in the carnivora the body is longer. The head of the herbivora is much larger than that of the carnivora. Herbivora are known to reach an age of up to two hundred years (elephant). Carnivora die very much earlier. Compare side by side the giraffe, elephant, camel, ox, horse, sheep, goat, with the lion, tiger, bear, fox, cat, and see the height attained by the first, exclusively vegetarians; see how proportionately they are built, their height equalling the length of their body, whereby the best of all proportions, that of a square, is given to them, and observe the shortness of legs in the carnivora. In all of these latter, the body-length is greater than their height. The mastodon and other prehistoric, very large animals, were herbivorous, as seen by the formation of their teeth. Here, certainly, nothing else but the difference in nutrition can make that diversity in appearance and character of those animals, those children of nature upon whom civilization and progress of science cannot pour its enlightening rays. Climate and altitude have no influence here either. For both herbivora and carnivora live in the same woods, on the same mountains, in the same valleys, and necessarily the carnivorous must live where the herbivorous exist. Heredity could be brought up here probably better than in man, but of whom did the first carnivorous animal inherit his shortness?

Not only, however, does the animal kingdom give us more than sufficient proof of the fallacy of any other theory than diet as the cause of height, also the ethnography of man, who has not yet been brought into intimate connection with the civilized world, proves it with certainty and positiveness.

Even at the present time, almost debarred from any industrial and commercial intercourse, many human tribes exist who are restricted to the products of their own land only, who have to live upon what only their own country grows—many human races who know nothing of agriculture either of their own fault or that of their climate. The blessing of the rapid railroad train, that medium which serves as an equalizer and rapid distributor of the goods and products of one country to others, that medium which makes failure of crops of one region unfelt by the immediate introduction of superabundance from elsewhere, are as yet unknown to many peoples. Many of these yet live in a primitive state, varying in their daily habits only very slightly or not at all, and consequently can be studied and inferences from them can be much more readily and easily drawn than from civilized people, whose habits regarding diet are much more complex. Such primitive races are found in the North as well as in the South, and like these extremes of climate also those tribes are extremes in regard to their nourishment and consequent height. The one occupying the North, the Esquimaux, Samoyedes, and the Lapps are the races known as the shortest; the tallest known are the Patagonians and Polynesians, who inhabit the South. What a difference of diet in those extremes!

Fr. Müller (Reise der österreichischen Fregatte Novara um die Erde, Ethnographie, Wien, 1879), gives us the following account: The nourishment of the Polynesian was always predominantly of a vegetable nature. Roots of ferns, berries, cabbage-shoots, bread fruit, cocoanut, manioc, and sweet potatoes formed the chief nourishment; animal products were taken seldom, as a rule only at festivities.

From Friedrich Ratzel's Völkerkunde I took the following extracts: The Hyperboraci do not belong to the tall-grown. A Samoyede—a tribe of Northern Siberia—of 150 ctm. height, Middendorf regards as tall among the dwarfs. The shortness of legs of all these races is striking, to which shortness of legs, in the case of the Lapps, also shortness of arms corresponds. The best foods preferred by them are: Reindeer flesh, dried blood, the contents of the stomach of the reindeer, eggs, some roots, and mossberries. In another chapter, treating of the same short people, he says: "Fishing is the chief source of nourishment besides hunting and reindeer breeding. The nourishment of the nomads of North Asia is preeminently of an animal nature. The Obongos, a family of African dwarfs, are experienced hunters; their nutrition consists predominantly of animal matter."

Rev. S. W. Kölle relates, in his "Polyglotta Africana," that a man of Pati, the residence of Bayon (landinwards of Cameroon), told him, there lived at the sea Liba, a tribe only three to four feet high; Kenkob was their name, strong people, excellent marksmen, peaceable, and very liberal men, who lived from the results of their hunting.

According to Emin Bey, who in the year 1882 came in contact with the Akkas, a family of dwarfs in Central Africa, his measurement of a twenty-four year old man gave a height of 124 ctm., and that of a thirty-five year old man 136 ctm. height; they are a good and genuine hunting tribe.

Do not these extracts from very competent authorities give us the true and the most satisfactory evidence that to the nutrition, that to the diet only, the height of man is to be ascribed? that the tall man is indebted for his body length to the abundance of vegetables he takes, and that the exclusive animal diet, the insufficiency of the earthy salts, keeps back the development of the skeleton, keeps back, restricts the growth of bone, and thus is the cause of the short man? Does it need any better or more convincing facts?

I myself have not yet failed in correctly telling a person his likings, whether he rather ate vegetables or meat, which I inferred from his stature; the above theory proved to be correct, proved to be a fact in every instance without exception. The short man is fond of meat, without which he says he could not live; indifferent to it is the tall man. "I must have soup and vegetables every time; about meats I don't care very much," the latter says. "If I should always have my own choice," one tall man told me, "I would always take vegetables."

Of two children, both girls, the one living in our house, the other the child of a friend of our family; the first being about three, the second about five years of age; the first child is strong, robust, fat, and large for her age, the second is small and thin, and everyone remarks "she never grows." As to their diet, the first one, says the mother, eats much potatoes, bread, soup, and vegetables, little meat; the latter gets no vegetables at all, or only very seldom, although she takes them, if given to her, with great avidity, and must be forced invariably every time to take meat, which the child gets every day, sometimes several times during the day. Another fact—Mrs. F——, thirty-five years of age, rather above woman's average height, not exactly tall, corpulent, and strong, when asked whether she liked and ate much meat she replied in a certain tone of pride and self-reliance, "I don't relish meat at all, I must have potatoes at every meal and enough of them; very often I leave the meat untouched. I never did care for meat." Also other vegetables and cereals form factors of her meals. Her husband is tall and shares the same views with his wife regarding diet. What wonder if her children (boys), are also tall. Is it heredity? Have her children inherited the tall stature of their parents? No, decidedly not. "A bove majori discat arare minor." As infants and in early childhood they were simply brought up to the same conditions as favored by their parents, as their parents, judging from their own likings, thought wise and correct; they were subjected also here, as in many other cases of supposed heredity, to the influence of the same causes that typified their parents; also they have received largely a vegetable diet, considered by their parents as the proper one, they were not asked but given, and of course, as to be expected, the same conditions obtained.

The rejection of meat, so common in pregnant women, and coming on about the beginning of the third month, *i.e.*, commencement of ossification in the fœtus, and at the same time "the capricious appetite, which assumes the form of longing for strange and even disgusting articles of diet" (Playfair) are again proofs for the insufficiency of vegetables, of the bone-forming salts, in the then present condition of the woman's system.

Not only is height dependent upon a vegetable diet, also longevity and mental development are largely influenced by it. This we may infer from the fact that people in bygone years and centuries, at a time when meat was consumed much less generally and in much less quantities, than is now, not only were larger but also lived longer. It is self-evident that a structure constantly being kept in repair, a building whose main walls of support are constantly looked after, and any damage, slight as it be, immediately remedied, will naturally last longer. Again, it is also known that the first to suffer, in another building left to itself, are those parts upon which the safety of the house rests and not the façades or any other ornamental work. Just the same is in man. Bone is the first to show signs of weakness when all other organs still do their work satisfactorily. This, however, is conjecture, and even if vegetables are not the only causative factor of longevity, a factor they certainly are.

Regarding their effect upon the mental faculties, vegetables seem to be of a negative nature. Here again the herbivora and carnivora give us satisfactory proof; higher mental development we find in the carnivora.

To account for the necessity of vegetables to height is easy enough, but I could not yet find any reason why meat should have that effect upon the brain that it does have unless that it is reasonable to judge *a priori* "food of a higher organic development must also bring forth higher mental development." Or, the more readily coal, wood, or any other material burns, the larger and brighter is the fire. The more readily the food brought into the stomach is burnt up, digested, the brighter is also the fire here, and since meat is more readily and completely digested and assimilated, the greater probably is its stimulating effect upon the nervous system. (The fluid in the cerebral ventricles consists almost exclusively of sodium chlorid. Is it the greater quantity of the sodium that is taken in with the animal diet that stimulates the brain? Sodium predominating in animal, potassium in vegetable tissue.) In the case of the two children related above, the small one—fed mostly on meat—evinces remarkably high mental faculties for her age, whereas the other, the large, with a vegetable diet, shows nothing of sharpness of mind; in fact rather the reverse is true. We had delight in talking to the first—smaller child—as soon as she could express herself distinctly.

So much for what we may call the physiological effects of vegetables. Now let us consider their pathological influence, if used in insufficient quantity or ill proportion.

The deleterious effects of abstinence from vegetables for a length of time has been recognized already in scurvy. But also in rachitis, lack of earthy salts, *i.e.*, insufficiency of vegetables, is doubtless the cause. Such was my opinion, such was my conclusion about a year ago when after some time of observation I noted the fact of the influence of vegetables upon growth, and only a few weeks ago when looking around for some book which treated of the chemical analyses of food stuffs and found Koenig to answer my purposes, I read in the same book the confirmation of my views by several authorities; also according to these, insufficiency of vegetables causes rachitis, not the lactic acid. Following are the extracts taken:

Experiments by F. Roloff[1] prove that in young growing animals with insufficiency of lime and phosphoric acid, diseases of the bones always manifest themselves, and that, the stronger and sooner the greater is their insufficiency. Also the many experiments by E. Voit and Fr. Tuczek[2] gave the same results. The researches of Hofmeister and Siedamgrotzky[3] prove that the addition of more or less lactic acid, given together with enough of calcium phosphate (hay) produced no such symptoms as are characteristic of osteo-malacia or rachitis, a disease due to lime insufficiency." Rachitis is

[3] Mittheil aus d. chem. phys. Versuchs station d. Thierarzneischule zu Dresden.

a disease of the children of the poor, who in the larger cities cannot afford to buy vegetables, which are there much more expensive than meat. These poor children are fed largely on beans, peas, meat, and potatoes; the relation between albumin and salts in the first three being nearly the same, and of the latter, the starch being the principal part, they cannot digest enough to give them the necessary quantity of salts. Osteo-malacia is also common in "women who have borne many children," *i.e.*, women who had to give off bone elements from their own constitution to supply the demand of their developing fœtus.

Gout is another disease acknowledged to be due to a high nitrogenous living among others, also to excess of meat.

Laboring under the impression that excess of one means diminution, insufficiency, of the other, that therefore excess of meats means insufficiency of vegetables, I had the opportunity to experiment on a gentleman, Mr. N——, whose urine I examine every month. This is the history: The first analysis I made on May 2, 1892, when I looked for albumin, sugar, excess of phosphates, and although the color of the urine did not indicate any bile or blood, yet I did it for the sake of thoroughness. Regarding these I found nothing abnormal. On July 19th followed the second analysis, when I looked for the same and found the same as on May 2d. The third analysis, on August 16th, resulted similarly. On September 20th, however, I recognized hyperacidity, which led me to look for excess of urates, which I found. Being asked by that gentleman the cause of the excess of urates, I answered, it may probably be due to the bottle, which was not the same as the other three times, and which contained some kind of drug before it was filled. On October 15th I found nothing abnormal; whether it was a faulty analysis or not I could not tell. But the following three analyses, those of November 12th, December 24th, and especially that of February 4, 1893, were charged abundantly with excess of urates. Mr. N—— asked me what harm might arise, to which I responded, it may lead to stone in the bladder or gout; and as his brother has already had several attacks of gout, I told him he was likely to get it unless he changed his diet, which consisted of meat three times a day, and some spirits; of vegetables, which he absolutely disliked, he took very few potatoes. My advice was, not to stop his meats, beer, or wine, but to have plenty of vegetables at every meal, which of course itself must diminish the quantity of meat, the stomach having been satiated already by vegetables. Mr. N——, who is a graduate of the City College, a member of a downtown wholesale firm, and of good social standing, thought there was a difference between fluid and solid meat, abstained from the first, and with the latter he took sufficient vegetables. I was surprised not to find any trace of excess of urates at the next analysis, March 18th, since which time the urine remained normal, Mr. N—— now being fond of vegetables.

The deposit of urates in the joints may probably be due to the following chemical changes: Uric acid, an animal product, found only in the carnivora, not herbivora, is produced only by animal and not by vegetable tissues. Consequently an increased supply of the material will increase the quantity of the output, *i.e.*, increased animal diet will increase the volume of uric acid in man. Finding no substances which, if vegetables were taken the free sulfuric acid contained in them would counteract, the excessive amount of the uric acid circulating in the body, combines with the sodium (which with increased animal diet is also increased) of the synovial fluids to form the urate of soda, which is deposited. That the great toe is usually first to be involved may be due probably to the fact that the great toe joint is the least disturbed or exercised of all the other joints in the body and therefore any formation of deposits is undisturbed.

Related to gout, the difference being probably one of degree, is rheumatism. Here, as in gout, the joints are the site of disease; here, as in gout, there is "hyperacidity," or diminished alkalinity of the blood; here, as in gout, exists an ill proportion between meat and vegetables. Of the four patients I saw in Bellevue, 1, John C. O'C——, aged forty three, admitted October 1, 1893; 2, Charles B——, admitted September 21, 1893; 3. Nicholas M——, admitted March 22, 1893; and 4, Alfred K——, admitted October 2, 1893—there were no more in our wards at that time—everyone preferred meat, which they had taken several times a day, almost abstaining from vegetables; also to them meat was the nutritious food, the diet. In gout the excess of meat is apparent, easily detected, in rheumatism, a disease more of the lower class, the deficiency of vegetables is of a slow coming character. That in fishermen exposure to wet and cold should be regarded as the cause is not necessary; these people live on an animal diet almost exclusively. How well can each of the symptoms of rheumatism be explained should insufficiency of vegetables, or what is the same thing, excessive consumption of meat—the cause of the hyperacidity—be considered the etiological factor. Skin diseases and all other diseases that are the result of hyperacidity of the blood may thus have for their first, predisposing, if not exciting cause, an ill proportion between meat and vegetables, the predominating one being meat.

If the foregoing be recognized would we not be just in saying that as well as excess of meats, also excess of vegetables must induce sooner or later a pathological condition? that excess of vegetables or diminished quantity of meat, may be the idiosyncrasy, predisposing or exciting cause, of another class of diseases?

Surgical Suggestions.

A. C. E. Mixture.—I fully believe it to be as safe an anæsthetic as any, and one by which the dangers of chloroform and the inconveniences of ether are alike avoided.—Reeves.

Sponges may be made aseptic after use, but there is no known agent on which we can rely to counteract possible toxic albumoses and ptomaïnes.—Mayland.

Cancer.—Belief in heredity is derived merely from popular tradition, and is wanting in any sound basis of scientific proof. Extremely practical issues are involved, and the views now prevalent often lead to disastrous results.—Snow.

Thiersch's Solution, which is not irritating, as the other antiseptic fluids are:

℞ Salicylic acid..... ʒ ss.
Boracic acid..... ʒ ss.
Aquæ..... O. viij.

Labyrinthine Disease due to secondary syphilis, occurring after the appearance of pharyngeal mucous patches and simultaneously with the roseola, without implication of the middle ear, is reported in a case recently seen by Toeplitz.

Tenorrhaphy.—Where a gap exists, no matter how slight, in the continuity of a tendon, we should never sew the ends together, under the impression that a slight shortening will do no harm. Any shortening, however slight, of a flexor will be sure to prevent complete extension of a finger, and *vice versa*.—Lund.

Rupture of the Male Urethra.—The suprapubic method should relegate the uncertain perineal method of treating this dangerous injury to the same obscurity that the suprapubic method has relegated the perineal method of extracting stone from the bladder.—Stewart.

Epithelioma of superficial variety—alternate applications of ten per cent. methyl-blue and twenty per cent. chromic acid.—Darier.

Symphyseotomy.—The writer concludes, after two operations and some investigations on the cadaver, that not more than two centimetres separation of the pubic joint follows simple division of the articulation, while by section of the ligamentum arcuatum inferius the joint will separate to the extent of 5 to 6 ctm.—DÖDERLEIN.

Pneumonectomy.—One great difficulty will be to determine the cases that are suitable for pneumonectomy. It is said that in the living collapsed lung foci of disease are readily detected by palpation, and many portions might be ligated and removed if necessary.—LAWSON.

Indications for Cholecystotomy.—Frequently recurring biliary colic without jaundice, where medical treatment has failed. Persistent jaundice where the onset is ushered in with pain, and where recurring pains, with or without ague-like attacks, render it probable that the cause is gall stones in the common duct. Distended gall-bladder from impaction of calculi in the ducts. Empyema of the gall bladder. Persistent jaundice with enlargement of the gall bladder dependent on some obstruction in the common duct, even where the cause cannot be clearly made out.—ROBSON.

Perityphlitis.—In 112 cases of perityphlitis, in which post mortem examination was made at the Berlin Anatomical Institute, 24 were found due to coproliths, 4 to foreign bodies, 29 to ulcerations. In 459 cases collected from literature coproliths were present 179 times, foreign bodies, 16. Perforations of cæcum are rare, being found 29 times in 218 autopsies. Four to five per cent. of those affected die.—RENVERS.

Metritis may give symptoms referable to the kidney.

Chloroform Syncope.—The heart cannot be weakened under chloroform except by interference with the breathing. It is useless and dangerous to take the pulse as a guide. Watch the respiration. Safety is insured only by regular natural breathing.—LAWRIE.

Supra sphincteric Ulcers of the Rectum require the galvano cautery under anæsthesia and with the aid of a speculum. Boric-acid lotions and iodoform tampons may be used in the after-treatment, and antiseptics, such as naphthol, administered internally.—QUÉNN.

Guushot Wounds.—Recent fractures and dislocations of the spine should be operated. The large mortality should not deter, since cases that would surely die or recover hopelessly paralyzed may be saved.—PHELPS.

Rosacea.—

Ichthyol	2 parts.
Resorcin	1 part.
Collod. flex.	30 parts.

—PETRINIO.

Tubercular Ostitis of the Knee in Children (white swelling).—It has long since been established that the growth of bone is seriously interfered with by excision, and surgeons, as a rule, avoid operating on the knee-joint. The cases that I have presented lend additional weight to the argument against the operation. The appearance of sinuses, the infiltration and distortion of the limb, seem to demoralize the surgeon at times, and he feels that only an incision will save life.—GIBNEY.

Cancer of the Uterus.—Total extirpation is destined to be the operation for cancer of the uterus, whether the disease is cervical or corporeal, and if done in time will permanently cure a certain portion of cases. If any tissues adjacent to the uterus are already involved, it should not be attempted.—LEWIS.

Too Small Doses of arsenic are usually given. In skin diseases the sufficient dose is the one the patient can stand. Arsenious acid is the best tolerated. Diascordium facilitates tolerance. One grain can be ordered with one-sixtieth grain of arsenic for each pill.—BESNIER.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MR. HUTCHINSON'S CLINICAL CONFERENCES—NOTES OF HIS VIEWS ON SOME CASES OF SKIN DISEASES EXHIBITED—RED ECZEMA—BAZIN'S MALADY—HERPES—SENILE SCROFULA—LEUCOMA OF THE TONGUE—MOLLUSCUM CONTAGIOSUM—RECOVERIES FROM LEPROSY—CHRISTMAS IN THE HOSPITALS—A FEVER HOSPITAL PROPOSED CLOSE TO A MILITARY HOSPITAL—QUESTION IN PARLIAMENT—SANITARY REPORT OF EGYPT—COMPULSORY NOTIFICATION—DEATH OF PROFESSOR BENTLEY.

LONDON, December 27, 1893.

I HAVE in a former letter (MEDICAL RECORD, November 18th), described Mr. Hutchinson's new museum, and intimated an intention of recording some of his remarks at the clinical conferences he is holding there. The following notes, selected from his observations at four different demonstrations, will redeem my promise, and give your readers some idea of these interesting meetings.

A girl, aged eleven, on whose right leg red eczema appeared, was one day exhibited. The skin of the whole body had from time to time been attacked. The appearance was suggestive of inflammatory icthyosis, but it was pointed out that that would affect the whole surface at once. The rather trite observation was made that eczema is always worse in hot weather, and aggravated by soap and hard water.

Erythematous patches on the legs of a woman aged thirty two, first appeared a year ago, about two months after her last confinement. Some of the patches had ulcerated. There was no history of tubercle, and no other part of the surface was affected, so that the case resembled Bazin's disease, of which a case was exhibited another day in an anæmic young girl. On both of her legs were indurated nodules between knees and ankles, and there was no ulceration, so that this case was more like those described by Bazin some twenty-five years ago, under the term "indurated erythema of scrofulous persons." English dermatologists are becoming interested in these cases of Bazin's disease, which may be described as small, hard knots under the skin of the legs in young persons, looking like erythema nodosum but not painful, and as often on the back of the legs as the front. But Bazin never mentioned ulceration, and this Mr. Hutchinson suggested might be because as a physician he was not consulted for ulcerated legs, and when his cases passed to this stage they might go to surgeons. The multiple ulcers strongly resemble those of a syphilitic type, and Mr. Hutchinson confessed that a case he had related in his books on syphilis he now knows to have been free from that disease, although at the time he treated it as such. It is good to hear skilled and patient observers acknowledge mistakes, and may well stimulate all to be careful. In this case mercury was administered for two years, but seemed to suit the patient rather than injure, thus confirming Mr. Hutchinson in his belief that mercury given judiciously is not injurious to strumous persons. In this belief I am inclined to share, but it must be judiciously given. If the patient improve and gain flesh, it is well; but if the contrary occur, the drug should be at once omitted. Multiple ulcers in scrofulous persons (sometimes in healthy ones), limited to the leg between the ankle and knee, are the characteristics of Bazin's disease. It is quite exceptional to find induration above the knee. Sometimes the disease appears behind the upper arm. Pustular ophthalmia is a common complication, indicating again the connection with scrofula, which Mr. Hutchinson distinguishes from tuberculosis, regarding it as that state of health which renders a person susceptible to the attack of the tubercle bacillus. The reason the legs are the seat of Bazin's disease he attributes to some defect of the circulation, though it must be confessed varicose veins are not associated with it,

nor for that matter is any known circulatory change. He also thinks there must be some infective influence from the first ulcer, as when one forms others occur. But what causes the first? He suggests the sting of some insect, and we know how severely such injuries act on some persons. He thinks, too, that bromide or iodide may start the disease. As to treatment, he puts the patients to bed for a few days, and then sends them out to be active in the fresh air or to the seaside. The legs he keeps moderately bandaged, and dresses the ulcers with an ointment of hydrarg. bisulphuret, four grains to the ounce. The great thing is to improve the general health.

Herpes affecting the digits is rare, but Mr. Hutchinson showed a case in a married woman, aged about thirty, who during the last three years had suffered from attacks again and again. The recurrence seems to come at shorter and shorter intervals; now not more than six weeks intervene. It is the ring-finger of the right hand which is affected, and each attack lasts about ten days. A six months' course of arsenic was recommended. In contrast with this localized case I may cite a more extensive one shown another day, which occupied the course of the posterior branches of the cervical nerves, and on which the remark was made that shingles gives us anatomical instruction, and that anatomists had gathered some minute details from the way in which the eruptions followed the course of nerves.

Senile scrofula was the diagnosis in a man aged sixty-two, who had enlarged glands of the neck extending to the axilla. The swellings were quiescent and freely movable, the condition spoken of as the "bunch of grapes," thus excluding malignancy, in which "all the glands are glued together." The main point in tuberculous glands, Mr. Hutchinson said, is their infective nature, so that as soon as one becomes enlarged others follow suit, being successively infected, and this establishes the treatment, extirpation. But in this case the age forbids operation, though in young persons removal of glands likely to be infective is always to be attempted; even repeated operations may be performed if necessary. This man had a smoker's tongue, which is a superficial leucoma of the tongue, and another patient exhibited a more advanced stage of this, the so called "white-paint condition." The man had old syphilitic scars on his face, and Mr. Hutchinson remarked that when he was a student this sort of tongue was commonly attributed to three S's, viz., syphilis, salivation, and smoking. He considered that the term icthyosis was quite inapplicable to the disease, which begins as a superficial glossitis, and proceeds to the formation of white patches. Then sometimes the disease becomes epitheliomatous, so that if ulceration and a sore form operation should not be delayed; but while there is no solution of continuity there is nothing to be feared. A drawing illustrating this was exhibited of a tongue removed ten years ago, and the patient being still well.

Molluscum contagiosum is comparatively rare in adults, but Mr. Hutchinson has often been consulted for it in private practice by men, not once by a woman. All these men took Turkish baths, and probably contracted the disease there, though it was not easy to see how. The contagion might possibly adhere to the towels, but it is difficult to see in what way. It had been suggested that the profuse perspiration induced it, but in that case it would be disseminated, not just a patch or two, as it is found in adults. In children, however, the spots are multiple and diffused, showing a greater susceptibility in them. The disease is no doubt often taken by sucklings from their mothers, as the breasts of women are the favorite seat of the spots. It may last six or twelve months, but does not remain a life time, in which sense no one has seen it to be chronic.

In leprosy and recovery from it, Mr. Hutchinson still holds to the fish theory of causation. He says it is certain the bacillus must enter the body either in the food or by direct contagion, but that it is not transmitted by the latter, nor by heredity, and Englishmen who acquire the disease abroad may return home without risk of giving it to their friends. Those, too, who go to leprosy countries may acquire the disease without any exposure to contagion. So he concludes the bacillus enters in the food, and the only article of diet open to suspicion is fish. A patient was shown who had recovered from what, three years ago, Mr. Hutchinson had no doubt was true leprosy. The disease was contracted abroad. The brown patches have all gone, but of course the anæsthesia remains, and is a source of frequent injuries, but these always heal well.

Avoidance of "anything taken out of the water" for food, and three minims of Fowler's solution three times a day, has been the treatment during these three years. It was stated that the anæsthesia has somewhat diminished. A reference was made to other cases of recovery, one recorded by Mr. Hutchinson in the "Transactions of the Royal Medical and Chirurgical Society" for 1879. Another case was that of an officer seen ten years ago with undoubted leprosy, seen a second time lately for another affection, when the leprosy was found to have disappeared, but blindness remained from previous destruction of the cornea. The case of the man Yoxhall, which will be remembered as having no little influence in bringing about the leprosy commission, was adduced as a recovery, although his hands are much crippled, and he is still liable to some ulceration of both feet and hands; but Mr. Hutchinson attributes this to malnutrition of the skin. Another case was that of a young man, who so far recovered from leprosy as to return to his studies, but was afterward carried off by acute tuberculosis; and it was remarked that the bacillus of tubercle and the bacillus of leprosy being undistinguishable, are probably identical, although differentiated in some way yet to be discovered. This is perhaps why those lepers who have recovered generally become tuberculous. Lepers coming to England from a district where the disease is endemic may be said, as a rule, to recover, and careful investigations by American physicians have established the same rule for the United States.

LONDON, December 30, 1893.

During the Christmas recess not a few of the younger staff and students at our hospitals take a pleasure in helping at the entertainments which are commonly given to those patients who can attend them. The nursing staff is invariably to the front in the decoration of the wards, and as many donations of flowers and plants are presented the task of arranging them usually results in great satisfaction to the workers and much pleasure to the patients. A Christmas dinner is also a feature of hospital administration, and the patients who can partake of turkey or roast-beef are seldom the worse for it. Whether the same may be said for plum-pudding and mince-pies is another question. Perhaps the childrens' wards and the childrens' hospitals are the most pleasant to see during the festivities, for the little patients have of late been carefully catered for by various philanthropists, and their joy in the toys and other presents they receive is untinctured by the reflections that too often depress the adults.

A remarkable fact transpired in the House of Commons the other day. The Secretary of War acknowledged that his department had objected, but without success, to a proposed site for a new fever hospital which is to accommodate five hundred patients. The proposed site is said to be within one hundred and fifty yards of the National Military Hospital, at Woolwich! In connection with this fact I may remark that the great difficulty of obtaining suitable sites experienced by the Asylum's Board has also been the subject of parliamentary questions, and the statement was made that the Local Government Board dealt with every case on its merits, regard being had to the report of inspectors who inquired into the circumstances of each.

The first annual report of the Director-General of the Sanitary Department of Egypt, Dr. J. G. Rogers Pasha, is worth the attention of all sanitarians. As might

be expected it discloses a number of terrible defects in Egyptian sanitation, and points out the urgent need of various reforms. With a death-rate of forty, and this probably an understatement, one is prepared to hear of polluted water, foul soil, leaking cesspools, overcrowded dwellings, and other abominations. On the other hand a commencement of reform has been made and a better era may have been begun. Hospitals and dispensaries are at work. A pavilion for infectious diseases has been constructed at Alexandria. An attempt at registration of births and deaths has been made. Some towns are partly supplied with filtered water and other reforms, such as preventing cemeteries being established near crowded localities, are under consideration. Perhaps as much has been done as could have been expected in dealing with an Eastern people.

Mr. Hart, as chairman of one of the committees of the British Medical Association, has issued a special report, in the journal, on Compulsory Notification, of which he is a strong advocate. I can hardly deny that notification is just now in the ascendant, and perhaps the majority of medical men would support compulsion. But a very influential party would protest, and some of our most thoughtful physicians dislike the idea. But what strikes me as curious is the argument that if statistics of death-rates are of such great value would not attack-rates be equally so? But surely we might equally say that if attack rates of a few diseases are useful to science, so would be those of all diseases, and assuredly the people are not prepared to notify all their ailments for the sake of improving medical statistics. Even Mr. Hart is not prepared to include measles in notification returns.

Professor Bentley died on the 24th inst. at the age of seventy-two. He had a long and popular career as Professor of Botany at King's College and other institutions. He was also Professor of Materia Medica and Botany at the Pharmaceutical Society. I have known him more than thirty years, though, curiously enough, I never heard him lecture. Yet I have talked with those in whom he had kindled a great enthusiasm for botany. He was one of the editors of the British Pharmacopœia of 1885, and author of perhaps the best Manual of Botany for Medical Students—a manual full enough and accurate enough to serve as a ready book of reference throughout a career of practice.

THE PRIVATE-ROOM QUESTION IN HOSPITAL TREATMENT.

To the Editor of the Medical Record.

Sir: May I be permitted to trespass once more upon your valuable space in order to acknowledge that your criticisms upon my letter of January 8th are unanswerable?

In my letter I did not consider the private-room question in all its bearings. I believe that my statement is correct, so far as it goes; but it is correct only when applied to the subject of the relations of the medical staff of a hospital (considered simply in its official character—as a part of the machinery of the institution, not as a group of individual citizens) to the managing board of that hospital. That is to say, that the medical men on the staff of a hospital have no right to complain if they are called upon to treat any or all of the patients in it gratis. The managing board has a perfect right to make such rules as to it seem best for the conduct of its medical officials in this respect. The private room system may or may not be objectionable; but it is no hardship for the hospital doctor if he voluntarily accepts a position in a place where it is in vogue.

It is, however, a hardship for those who are not on the staff, as you justly remark. It is more than a hardship; it is a wrong. While it is the duty of the managers to administer their trust without regard for sentiment, it is no part of their duty to do so without regard for principle. Although bound to increase the income by all legitimate means, they have no right to do so by improper methods. Offering inducements to the patients of any doctor to leave him and enter a hospital is really little, if at all, different from stealing some of his money. The fact that it is done for the benefit of a charitable institution does not alter the case. It is probable that the income of any hospital could be much increased should its funds be invested in well-appointed liquor saloons, but the managers would justly object to such a way of getting money. Now the reason that such an objection is just, is that bar-rooms do harm to certain members of the community in particular, and demoralize the public at large. The same may be said of the private-room system; it injures the defrauded doctor, and it pauperizes (the word is correctly used)—it pauperizes to a greater or lesser extent the public.

Of course, when drawing a parallel between running a liquor saloon and keeping a sort of sanitarium, I disregard the legal questions involved. That the courts would forbid the former use of trust-funds is tolerably certain; I do not know whether the legality of the latter plan has been tested.

It seems to me, Mr. Editor, that the objections which you urge, and which are merely amplified in this letter, apply, not to the remuneration of hospital doctors, but to the whole private-room system. If the system is wrong, I fail to see how it is bettered by providing pay for the medical men who are called upon to treat patients who have been lured away from other doctors! It must not be forgotten that private patients always enter a hospital for the reason that they think to obtain some advantage not possible outside. While exacting pay for medical attendance would reduce the number of people who would leave their medical men and enter, some would be led to do so. Is there not some resemblance between the attitude of one who seeks to protect the outside practitioner to a certain extent only, and who does not object to the infliction of some wrong upon him, and that of the girl with the illegitimate baby who said in palliation of the act which resulted in the infant's advent, and in justification of her conduct, "that it was such a little one?" J. West Roosevelt, M.D.

New York, January 13, 1894.

[Yet as a little thing it was enough to prove the case. We still contend that it is not right to treat such patients for nothing in hospitals. An extra fee should always be charged by the attending physician or surgeon. The really poor are the only ones entitled to free treatment. —Ed.]

THE IMPLIED CONTRACT TO PAY FOR MEDICAL ATTENDANCE.

BY WILLARD A. MITCHELL, COUNSELLOR AT LAW, NEW YORK.

IN these hard times, when the physician sees nearly all of his patients trying to economize, and many of them apparently coming to the conclusion that the best place to begin is with the doctor's bill, he is apt to ask himself what his legal rights are, and to what extent he could, if necessary, enforce payment for his services through the courts. It is attempted in this article to state briefly some of the principles of law applicable to the inquiry, and to point out some of the leading cases by means of which the matter may be more fully investigated.

Little difficulty is presented by those cases in which there has been an express contract as to who shall be responsible for the bill, and what the rate of compensation shall be. But in the majority of cases no definite contract is made, and the parties are left to the contract implied by law.

Although medical services may be rendered under such circumstances as to impose no legal liability for compensation, the presumption of law is that such liability does arise, and the burden is upon the patient to show that the services were mutually intended to be gratuitous. (In re Scott, 1 Redf., 234; and see Smith v. L. I. R. R., 102 N. Y., 190.)

This is true even when the services were rendered voluntarily and without request, if they were accepted without objection. A mere intention not to charge for services, which intention was not communicated at the time to the person for whom they were rendered, will not prevent a recovery for their value.

If services are rendered gratuitously in the hope of a legacy or other benefit under the patient's will, no recovery can be had. But if one agrees to provide by will remuneration for medical services, equity will decree specific performance when the agreement was definite and certain, and when not, the value of the services may be recovered in an action at law. (Shakespeare v. Markham, 10 Hun, 322.) Recovery may also be had where no definite sum was agreed upon, and the provision made by will is inadequate. (Porter v. Dunn, 131 N. Y., 314.)

The right to recover for medical services belongs only to a duly licensed physician, and one not so licensed cannot recover even on an express contract. (Fox v. Dixon, 12 N. Y. Suppl., 257.) And a note received by him for his services is void for lack of consideration. (Holland v. Adams, 21 Ala., 680.) A physician is required to be licensed only in that county in which his principal office is located (Martins v. Kirk, 55 Hun, 474), and one duly licensed may recover for services rendered by his students or assistants, although the latter are unlicensed. (Waring v. Monroe, 4 Wend., 200.)

An exception to the rule that the presumption is in favor of an intention to compensate, prevails in the case of services rendered to a near relative, especially one living in the same family with the physician. No recovery can be had in that case, unless there is an express contract, or evidence showing that there was an expectation on both sides that compensation should be made. (Lynn v. Smith, 35 Hun, 275; Dye v. Kerr, 15 Barb., 444; Ross v. Ross, 6 Hun, 182.) But this exception does not extend to the case of a more distant relative, as an aunt or grandfather not living in the same house. (Succession of Dickey, 41 La. Ann., 1010; Walters v. Mahew, 30 St. Rep., 96.) The question as to whether services to a relative were intended to be gratuitous, frequently arises after a patient's death, and upon the settlement of his estate.

When there is no doubt that the services were rendered with an expectation that payment should be made, some uncertainty may arise as to who the person legally liable is. The law will cast this legal liability either upon the patient himself, upon some person who stands in such relation to the patient as to be liable for necessaries furnished to him, or, in some cases, upon a third person not under such obligation.

Those who stand in such relation to others as to be liable for necessaries furnished to them are husbands, fathers of minor children, and guardians. The obligation to support another may also arise by contract. Where one under such obligation summons a physician, or, knowing the circumstances, acquiesces in his rendering services, he becomes liable to pay their value. (Rundell v. Bentley, 53 Hun, 272.)

The liability of the father for services rendered to his children ceases upon their majority. So where an adult daughter was ill in her father's house, the physician was not allowed to recover from the father for his services, although the latter had been present at the rendering of the services and had said nothing to disclaim liability. (Crane v. Baudouine, 55 N. Y., 256.) It was even questioned if the father, in that case, would have been liable had he himself summoned the physician, the court citing with approval a Pennsylvania case (Boyd v. Sappington, 4 Watts, 247) in which a father summoned a physician to his house to attend an adult son, but was held not liable for the services. A husband, or the father of a minor child, may also be liable on the theory of agency, for necessary services rendered without his knowledge. While a father provides for his child, the latter has no implied authority to act as the father's agent in procuring necessary medical attendance for himself; but very slight circumstances will be sufficient to show such authority; as that the father had previously paid bills contracted by the child (Neilson v. Ray, 44 State Rep., 125), or that the father has sent the child to school at a distance and pays his expenses. (Baker v. Keen, 2 Stark, 501.) And a recovery may be had without showing any authority as agent, when the father has deserted his child or utterly failed to provide for it. (Van Valkenburgh v. Watson, 14 Johns., 480.) So also an infant, who has no parent or guardian, may be held personally liable for necessary medical services rendered to himself. (Kline v. Amoureux, 2 Paige, 419.)

No proof need be given of a married woman's authority to act as her husband's agent in procuring necessary medical attendance for herself and her family, as "it is presumed that the husband assents to contracts made by his wife for necessaries . . . which presumption can be repelled only by proof of express notice of previous dissent, or a notice not to trust the wife." (Mott v. Grunhut, 8 Daly, 544.) It is not necessary, in order to charge the husband, that the marriage be valid. It is sufficient if he has represented the patient as his wife. (McCutchen v. McGahay, 11 Johns., 280; Gerlach v. Turner, 98 Cal., 446.) Where, therefore, a physician is called in by a married woman, or renders services to her or her children, in the absence of any special agreement

on the part of the wife to pay, the husband is liable. (Estate of Mrs. Shipman, 22 Abb., N. C., 291.) But the husband is relieved from liability and the wife becomes responsible when she pledges her personal credit. (Ellison v. Sessions, 44 N. Y. State Rep., 644; Hallock v. Bacon, 45 N. Y. State Rep., 484.) Whether she has so pledged her personal credit is a question of fact for the jury. (Cutter v. Morris, 116 N. Y., 310.) The fact that the services were charged to her on the books, or a bill rendered to her personally, unless acknowledged or acquiesced in by her, is not admissible as evidence against her (Crane v. Baudouine, supra), and even if she acknowledged the bill and made payments upon it, the presumption is that she was acting as her husband's agent: and although it is some evidence that she has pledged her own credit, it has been held not sufficient to defeat an action against the husband. (Furlong v. Hyson, 35 Me., 332; and see also Meiker v. Claghorn, 44 N. Y., 352; and Foster v. Persch, 68 N. Y., 400.)

There are two cases in which, in the absence of an express contract, the physician may recover if either husband or wife has property. The first is the case in which a physician renders services to a woman not knowing her to be married. Here the husband is liable as an undisclosed principal, but the wife is also liable as an agent who has made a contract without disclosing the fact of agency, and either could be sued notwithstanding a previous judgment against the other for the same cause, if it had not been satisfied. (Cobb v. Knapp, 71 N. Y., 348.) The second is the case in which a married woman, who has been abandoned by her husband, or is living apart from him for good cause, renders him liable for necessaries furnished to herself and her children. Here the debt is that of the husband, and the wife may not be sued directly. But a judgment against the husband may be enforced against the wife's separate property, by an action instituted for that purpose. (Edwards v. Woods, 131 N. Y., 350, *obiter*.)

A third party, not under legal obligation to furnish necessaries to the patient, may be compelled to pay for medical attendance when he has made an express promise to do so, although no benefit to the promisor is shown; and where his agreement is that he shall be liable primarily, and not as guarantor, it is not required to be in writing. (Hanford v. Higgins, 1 Bos., 441.) An outsider who has not made a definite agreement may be held liable where the circumstances are such as to raise an implied promise. The question is entirely "one of the intention of the parties, as deduced from the facts and circumstances of the case." (Buck v. Amidon, 41 How. Pr., 370.)

It often happens, however, as is shown by the reports, that physicians, occupied with the professional aspects of a case, rely too confidingly on the moral responsibility of some well-to-do friend or relative of the patient, without taking the proper steps to hold him legally responsible. In the case above cited, the defendant, a wealthy New Yorker, received a telegram requesting him to summon the plaintiff, a physician, to perform an operation upon defendant's brother in Connecticut. Defendant called upon the plaintiff, showed him the telegram, asked him if he could go, and when answered in the affirmative, accompanied him to the patient's house, paying the travelling expenses of both. The patient was unknown to the physician, who had, however, satisfied himself as to the defendant's financial responsibility. The Court held that on these facts a verdict against the defendant could not be sustained. He had merely acted as agent, had disclosed the fact of his agency by showing the telegram, and the circumstances were not such as to render him personally liable. A circumstance of some weight, as an admission against the plaintiff, was the fact that he had rendered a bill to the patient personally.

In the later case of Bradley v. Dodge (45 How. Pr., 57, Common Pleas), the physician was more fortunate. Defendant called at plaintiff's office and left his card, with the following message written upon it: "Call on Mrs. Day, at No. 769 Broadway." From that fact alone, a promise was implied on the part of defendant to pay for all the services rendered by plaintiff during the patient's illness; the Court saying: "The defendant might very readily have screened himself from all liability by simply writing the memorandum on a blank card, or by adding . . . something that would have apprised the plaintiff of the fact that he acted in the transaction for Mrs. Day, as her agent." It seems somewhat severe to place upon one who goes to summon the doctor for a sick neighbor, the burden of explaining in full that he is merely acting as an agent in the matter, and to hold him personally liable if he omits to do so; and the above case was severely criticised for that reason by the reporter. It goes further than the cases in other States (Boyd v. Sappington, 4 Watts, 247; Williams v. Bricknell, 37 Miss., 682; Meisenbach v. S. C. Co., 45 Mo. App., 232); and that its doctrine might not be sustained by our own Court of Appeals is indicated by a dictum in Crane v. Baudouine (supra), the Court remarking that even if the father in that case had gone himself to summon the plaintiff to attend his adult daughter living at home, no promise to pay would have been implied. But it is not impossible to distinguish the case of Bradley v. Dodge from the other cases cited. The fact that the defendant therein left his own name and address, so obtruding his own personality in a way not necessary in one merely acting as an agent, may be considered as justifying the finding against him.

In cases where reliance is placed upon the express or implied promise of a third party to be responsible for the bill, it is necessary to distinguish between primary liability and liability as guarantor. The importance of the distinction is illustrated by a recent case in this city. Dr. A—— had been called out of town to attend Miss B——, who was afterward brought here to the house of a wealthy brother. The brother called upon Dr. A——, and said, "I desire you to continue your attendance upon my sister. You need have no fear as to your bill, for if she does not pay you, I will." This would have been a valid contract if in writing, but our statute provides that "every special promise to answer for the debt, default, or miscarriage of another person," shall be void unless in writing. When, therefore, after a long illness requiring constant attendance, the lady died, leaving no property, and the brother, although not denying his promise, refused to pay the bill, the doctor was without legal remedy. An unconditional oral promise by the brother to pay the bill would have been legally valid. In a case where dispute arises as to whether the oral promise of a third party was that the promisor should be liable primarily or only secondarily, or where it is sought to hold a third party on a contract implied from the circumstances, the fact that a bill had been rendered in the name of someone other than the defendant would be an admission of great weight against the plaintiff, unless he could show that it was by mistake. (Buck v. Amidon, supra.)

As to the amount of compensation, a physician must be paid the reasonable value of his services, which, in case of suit, shall be determined by expert witnesses, and no one but a physician may testify as to such value. (Mock v. Kelly, 3 Ala., 387.) This does not leave the decision of the question of amount wholly to the physicians themselves, as the jury are not bound by their estimates, but may act on their own "knowledge and ideas." (Knapp v. Monell, 4 Month. Law Bul., 91.) The plaintiff may show that his standing in his profession is high: and the financial ability of the patient may also be considered. (Lange v. Kearney, 4 N. Y. Supp., 14.)

The general rule that one who receives a bill or account, and retains it without objection, will be deemed to have acquiesced in its correctness, does not apply to a bill rendered for personal services without previous agreement as to rate of compensation. But where a part payment is made on such bill without protest, it becomes an account stated, which may be sued upon without giv-

ing evidence as to the value of the services rendered (Bronson v. Hoffman, 7 Hun, 674); and the bill need not have been an itemized one. (May v. Kloss, 44 Mo., 300.)

Where the bill has not been acknowledged to be correct, and no payment has been made on it, the physician is not estopped by the amount originally charged from showing that the services were worth a larger sum. An interesting case in this connection is Williams v. Glenny (16 N. Y., 389), in which a bill of $150 had been rendered for legal services. No payment was made upon the bill nor other indication of acceptance given. In a suit for the value of the services, the plaintiff was allowed to show that their real value was $500, and he was given judgment for that amount. In Harrison v. Ayres (18 Hun, 336), an architect recovered the amount of an increased charge under similar circumstances.

The question as to whether or not it is good policy for a physician to enforce, in the courts, his right to compensation, is one which must depend upon circumstances. Such suits are more common in large cities than in the country, for reasons which are evident The two cases last cited indicate a means of redress against a patient, who, out of consideration, has been charged less than the real value of the services rendered, and then puts the physician to the trouble of a suit to collect his fee.

114 Nassau Street.

SOME OBSERVATIONS ON THE ACTION AND VALUE OF HYOSCYAMINE IN NERVOUS AND MENTAL DISEASES.

A Personal Experiment with the Drug.[1]

By WILLIAM PHILIP SPRATLING, M.D.,

New York,

Formerly First Assistant Physician to the New Jersey State Hospital for the Insane at Morris Plains; Member New York County Medical Society and of the Harlem Medical Society of the City of New York.

The use of this drug in mental diseases, especially in the acute types where marked exhaustion is liable to occur, is not only of questionable value, but may do the patient material harm. In stating this opinion, I have in mind the manner in which the drug is used in many institutions for the insane, which is merely to quiet the frenzy of the patient.

In such cases large doses are usually hypodermatically administered; the desired effect promptly secured, and lasting injury often done the patient. I speak from an experience of five years in a State hospital for the insane, where from one hundred and seventy-five to two hundred acute cases were annually received.

For the purpose of further studying the largely unknown action of the drug, as regards its hypnotic properties, I administered to myself one fifteenth of a grain of the sulphate of hyoscyamine with the hypodermic needle. Its effects will be described later on.

Hyoscyamus, known also as henbane, is a European plant, but can be grown in some parts of the Northern United States. The drug depends for its active properties upon the presence of two alkaloids.

One is crystallized, having the chemical formula, $C_{17}H_{23}NO_3$, and is termed hyoscyamine. The other is an amorphous brown liquid, and called by Ladenburg, a German chemist, hyoscine. The former is isomeric with atropine. The latter while being isomeric with hyoscyamine, differs from it materially. Hyoscyamine can be split into tropic acid and tropine, while hyoscine can be split into tropic acid and pseudo-tropine. Both will unite with acids to form salts. The sulphate of hyoscyamine seems to be the form of the drug most frequently used to quiet the excitement of the insane, though of late years hyoscine has come into popular favor for the same purpose. The action of the two alkaloids is very similar, and for practical purposes we may consider them together. The dose, however, of hyoscine is very much smaller than that of hyoscyamine. The physiological action of the drug upon man may be briefly summed up as follows: Great dryness of throat and mouth; mydriasis; insecurity of gait; giddiness; muscular weakness: brief sinking of pulse-rate, followed by increased frequency, and possibly in some soporific.

In looking over the literature bearing upon the study of its supposed hypnotic properties, it is astonishing to find how widely at variance are the opinions of therapeutists of repute upon this point. Most experiments that have been made to determine its action in this particular have been confined to animals of the lower order, and to insane members of the human family.

Hypodermatically administered in doses of from one-twentieth to one-fifteenth of a grain, the drug produces such absolute motor paralysis, and so checks, for the time being, all manifestations of voluntary action that we may easily be deluded into the belief that sleep is actually present. Dr. H. C. Wood, in writing upon the physiological action of hyoscyamine, says: "Dr. Shaw, as well as many other alienists, believes that hyoscyamine acts as a soporific. Dr. Shaw's opinion only is given. Richter, in his studies upon normal man, noted no tendency to sleep from its administration. It is a matter for regret that full data of Richter's experiments are not given. Let us not forget, however, that his observations, so far as we can find, are the only ones that were made upon normal man, *i.e.*, men who were not insane; and especially should we not forget the additional and more important fact that Richter failed to note that the drug possessed any hypnotic virtues. The sulphate of hyoscyamine is recommended by Brown,[1] and confirmed by Germaine,[2] "to quiet the violence of, and produce tranquil sleep without disagreeable sequelæ in, acute mania, though without curative effects." It would be interesting to know just how these observers arrived at the happy conclusion that the use of this drug in acute mania was followed by no disagreeable sequelæ. Persons suffering from acute mania are usually not capable of making, and afterward stating, trustworthy observations upon the after-effects of medicines.

White says that hyoscyamine is a powerful cerebral and spinal stimulant. Biddle states that it differs from opium in its general effects upon the system, in its comparatively feeble hypnotic effects. Hare, in his "System of Therapeutics," states that the hydrochlorate and hydrobromate of hyoscine, employed hypodermically, have recently come into use as pure motor depressants. It is well known, he adds, that after the exhibition of a dose sufficient to cause complete paralysis, that when recovery occurs, it is complete. The fact that neither muscle nor the motor nerves are sensibly affected, shows that the paralysis was due to depression of the motor centres.

In the Medical Record for July 29, 1893, Dr. James Porter Fiske reports "Some Peculiar Effects from Large Doses of Hyoscine." Dr. Fiske first gave a man, forty years of age, who was suffering from acute alcoholism, one one-hundredth of a grain of the hydrobromate of hyoscine. It produced no effect. Forty-five minutes later the dose was repeated. This caused the man to doze for half an hour. This made one-fiftieth of a grain he had received in less than an hour. Nine hours after the second dose, one-fiftieth of a grain was again administered. In fifteen minutes the patient complained of his extremities feeling peculiar, somewhat "numb and prickly." He rose from the bed and attempted to walk, but after going four feet fell to the floor. His speech had become confused; markedly difficult; his voice husky. The pulse was 90.

Two and a half hours later his walk was again steady, and his speech clear. One-half grain of sulphate of morphia was then tried, with no better results. Hallucinations of sight now appeared, and some hours later he received the third one-fiftieth of a grain of hyoscine: with the same result as before. At no time had the

[1] Read before the New York County Medical Society, November 27, 1893.

[1] British Medical Journal, November 25, 1882.

[2] Congrès International de Médecine mentale, Paris, 1889.

hyoscine produced a hypnotic effect; the chief effects being motor paralysis, as indicated by loss of power in the extremities; sensory disturbances and impairment of speech, with some circulatory disturbances.

The dose given by Dr. Fiske, one fiftieth of a grain, is small compared with doses that are frequently given in hospitals for the insane. One-twentieth, one-fifteenth, and even one-tenth and one-fifth grain are in some instances boldly given.

Had Dr. Fiske given his patient a larger dose than he did, the result would have been more prompt and lasting. Motor paralysis, in our opinion, would have been all.

Hare states the dose of the sulphate of hyoscyamine to be from one-sixtieth to one-fiftieth of a grain, and of hyoscine from one one-hundredth to one-ninetieth, given hypodermatically; and by the mouth from one ninetieth to one-eightieth.

Hare adds that he has given one-tenth of a grain of Merck's hyoscine in twenty four hours, obtained from two different and reliable stores, without producing sleep, although the respiration was much quickened. Dr. Hare is also authority for the statement that when given in delirium tremens it may cause cerebral congestion and Cheyne-Stokes breathing, and adds that the applicability of the drug is limited indeed, and that untoward effects are common. Wood advises that the dose of the drug to be given at first should, on account of the unusual susceptibility sometimes met with, be less than the one hundred and fiftieth of a grain.

I have many times given as much as one-tenth and one-eighth of a grain of the sulphate of hyoscyamine. Let me add, however, that it was before I had much experience in the use of the drug, and knew but little of its true action. I recall the case of a young man, twenty years of age, who suffered from periodic mania, and whose maniacal outbursts were so fierce and persistent, that for ten days he received, hypodermatically, one-fifth of a grain of hyoscyamine every six to eight hours.

Another case I recall that came under my observation was one of acute delirious mania in a vigorous young Irish woman, twenty-six years of age, who was given one-eighth of a grain every twelve hours for a period of ten days. This amount was given her simply to keep her in a semi tractable condition. She was a person of wonderful strength and remarkable physique; she destroyed all articles of furniture in the room, including bed, bedding, and clothing, and would have done herself bodily harm had she not been put under the influence of chemical restraint. Mechanical restraint was forbidden. Manual restraint was out of the question, four attendants could not keep her in bed. The quantity of hyoscyamine she received merely sufficed to render her motor system partially inactive. On the tenth day of her illness, death suddenly occurred, and was attributed to overdistention and paralysis of the heart. The autopsy, made six hours later, showed the heart enormously distended with partially clotted blood almost as black as tar. The heart-muscle was pale and extremely friable. The vessels of the scalp, of the coverings of the brain, and of all the abdominal organs, were greatly distended; the blood being almost black, and of a watery consistence. The lungs were in a condition similar to that of the first stage of the pneumonic process. It would be a delicate matter to decide just how far the drug was responsible for this woman's death. That it was a potent factor in causing it we can never doubt. When death occurs in the course of an acute mental disease like this, we always find, on post-mortem examination, evidences of congestion throughout the body, and particularly in the brain, but we do not find such plainly marked evidences of poison as were noted in this case, and shown especially in the condition of the blood.

With the object of knowing something more definite of the physiological effects of the drug, I took, at nine o'clock one evening in May, 1890, beneath the skin of the left forearm, one-fifteenth of a grain of the sulphate of hyoscyamine. A stinging tingling pain immediately followed the withdrawal of the needle, and ran rapidly down the ulnar side of the arm, and caused a burning sensation and numbness that involved the fourth and outer half of the third fingers. In five minutes a decided fulness in the head was experienced; objects about the room began to appear hazy and assume a wavy outline. Walking into an adjoining room, I sat down, and while stooping over in the act of untying my shoe, as I felt the need of going at once to bed, I pitched headlong upon the floor. At that moment began what has been termed a "jolly delirium." The fact that I had fallen headlong upon the floor appeared to strike the keenest chord of humor, and provoked, on my part, immoderate laughter.

After many fruitless and powerful efforts I succeeded in getting into bed. My reason at this time was in no way affected. I counted the pulse-rate, and found it to be about 90. Respiration was appreciably increased. It occurred to me to test cutaneous sensibility, which I did by pinching, as hard as I could, the skin of the right leg, above the knee. No pain whatever was felt; only a sensation as if some blunt object was being pressed against the limb. Tests at other points showed the loss of sensation to be general, though not in so marked a degree as over the lower extremities.

Twenty minutes after receiving the drug, motor paralysis was complete. The lower extremities were first affected, then the power to move the body, as sitting up in bed. Then the upper extremities; and finally, movements of the head became impossible. The grosser movements suffered first. The arms and fingers could be used with a degree of ease some moments after the lower extremities had become absolutely paralyzed. A furry feeling in the mouth and over the tongue, as if the parts had been scalded, was due no doubt to central sensory paralysis; and on this point I wish to say a few words later on. The faculty of speech became involved fifteen minutes after taking the drug, and was first shown by leaving off parts of long words; then mincing and cutting small words in two; and finally, no sound save mumbled and unintelligent whispers could be made, and these soon disappeared entirely. Motor and sensory paralysis was now complete. This condition of absolute helplessness lasted about four and a half hours.

At no time, however, was sleep present; at no moment did I become unconscious of my surroundings. The condition of jolly delirium, referred to above, was still present, and as the check that had been put upon motor activity began to disappear, mental confusion increased.

A homœopathic colleague who happened to be visiting me on this occasion, and who did not know of my rash experiment, recognized the effects of hyoscyamus in my symptoms and prescribed that drug for me in one one-hundredth grain doses.

All manner of strange and fantastic fancies, delusions and hallucinations, crowded before my vision, and presented themselves to normal reason and intelligence as actual living realities. This jolly delirium, in the course of two hours, passed into a more active and agitated delirium. The pleasant features all passed from it. It became painful and disagreeable, and then horrible. Every instant some new picture would be flashed before a distorted field of vision, and some horrible delusion force itself upon my consciousness. A condition of double consciousness was present. Normal reason, judgment, and personality took no part in these weird and fantastic fancies. They stood apart, apparently unimpaired, realizing and recording what was transpiring, and so vividly were they presented, and so firmly recorded, that almost every fancy, delusion, and hallucination can be recalled after the lapse of nearly four years.

Eight hours after the drug was taken all evidence of motor disturbance had passed away. Much sensory disorder, however, was still present. Hallucinations of sight remained for twenty-four hours.

Let me again repeat and emphasize the fact, that dur

ing all this time I did not sleep. Cerebration had been driven from its normal channels; not into lessened activity and repose, but into intense and maddening activity. Images, unstable, imperative conceptions, and distorted ideas sprang for hours from a congested and poisoned brain.

The condition brought about in the sensorium by the action of the drug was as opposite to the condition that is now almost universally believed to be present during sleep as it could possibly have been.

Nothing could be more unqualifiedly disagreeable than the after-effects of the drug. The disturbance of vision, which lasted for days after, was the least disagreeable of them all. The mouth was devoid of all moisture, save a slight, sticky, and unpleasant secretion, the product of the buccal, salivary, and parotid glands that had undergone chemical change. The drying up of the secretions of these glands, which are so essential in food digestion, is in itself alone a strong argument against the use of the drug in exhaustive diseases where nutrition plays so important a part. Not only do the secretions of the mouth suffer, but we have no reason for believing otherwise than that the glands throughout the alimentary system are similarly affected.

Headache, general and persistent, is another most unpleasant after-effect.

In reference to the action of the drug upon the sensory centres in the cortex, this experiment seems to have been of considerable interest. It furnished another link in the chain of evidence that has been produced to show that the sensory and motor centres in the cortex are most intimately connected.

Dr. Charles L. Dana reports, in the MEDICAL RECORD for May 13, 1893, an interesting and valuable experiment to determine the identity of the two centres. The experiment was made upon a man who suffered from hereditary chorea, and who had been trephined and a piece of skull removed from the right convexity, at a point over the middle part of the pre-central convolution and the parts in front. Four months later Dr. Dana made the experiment by using cocaine, and thrusting two long, sharp, insulated needles into the shoulder and arm centre. Turning on the current and manipulating the needles a little, convulsive movements of the left arm and shoulder were noted. The electrode was withdrawn, and the patient questioned as to his sensations. He said at the time of the movement of the arm he felt in it a numbness and heaviness; and otherwise described the feeling as though it were much the sort of sensation produced by pressure upon the nerve. The experiment was repeated with a stronger current, when movement of the left arm and leg and face occurred with much more violence. After this the patient said he had felt a sudden numbness in the left arm and shoulder. He experienced no pain, either peripherally or locally. From this experiment, and the fact that hyoscyamine, which we know is the most absolute and powerful motor paralyzant, and from the fact that it destroys the sense of feeling, we are justified in believing that the cortical centres of motion and sensation are identical.

Little remains to be said about the use of the drug in general diseases of the nervous system. Here, too, I believe its field of usefulness is small. It has been used a good deal in diseases characterized by tremors and mild convulsive movements, necessarily of central origin. In paralysis agitans of long standing it often does good in a limited degree, given in one two-hundredth grain doses, and not too often repeated.

Its action is to lessen the violence of the tremors by suppressing the motor area in the brain. It is doubtful if it possesses curative virtues.

In some forms of chronic diseases of the mind, notably in chronic mania, or terminal dementia, where some continual restlessness is present, and where the patient's physical condition is good, it may be of service in very small doses. In such cases I have more often ascribed the good results that followed to the moral effect of the needle in giving the drug than to the action of the drug itself. The conclusions I have reached as to the use of the drug are as follows:

1. That it should never be given in doses of any size in acute diseases of the mind.

2. That it should never be given in any disease in which the least degree of inflammatory action, or congestion, is going on: especially in the brain or its membranes.

3. That it should not be given to a patient who is exhausted, or in cases where exhaustion is likely to occur.

4. That it should not be given in any case for the purpose of producing sleep. It has not been shown by any authority that it has any hypnotic properties.

5. That its use is advisable only in chronic diseases of the nervous system, to quiet excessive tremor, and in chronic diseases of the mind where motor disturbances take precedence over disturbances of the sensorial centres.

70 WEST EIGHTY-EIGHTH STREET.

WHAT IS THE SITE OF INFECTIONS CAUSING EPITROCHLEAR GLANDULAR ENLARGEMENT?[1]

BY HOWARD LILIENTHAL, M.D.,

ASSISTANT VISITING SURGEON TO MT. SINAI HOSPITAL, LECTURER ON SURGERY TO THE NEW YORK POLYCLINIC, ETC.

IN answering this question I shall use notes on cases which have all been under my own observation. No case, however, has lacked confirmation by at least one other physician.

All doubtful cases, *e.g.*, where infection or adenitis was bilateral, have been discarded unless the clinical features were quite unmistakable.

My experience has been with the various forms of ordinary suppurative infections, with pseudo-erysipelas, with epithelioma, and with one unusual case of syphilis.

No finger chancre appears in my table, but it seems to me that syphilis, under such circumstances, might be presumed to follow the path of other infections.

Observation as to the axillary nodes has not been fully carried out, but I believe that any infection of hand or arm may cause their intumescence.

Taking with the cases in my list very many others which, for one or another reason, I was not able to use in this paper, I cannot help feeling convinced of the correctness of my conclusions. They are the following:

A. Cubital lymph-node enlargement is probable,

1. Where an infection enters on the dorsum of the hand or wrist anywhere from the finger-tips to the forearm. 2. Where an infection enters anywhere from the styloid process of the ulna to the tip of the olecranon, in that region where the bone is nearest the surface. 3. Where volar infection involves the deeper tissues.

B. Cubital lymph-node enlargement is improbable in superficial volar infections.

Forty one cases have been tabulated. Eleven are anterior, twenty-nine are posterior, and one is doubtful, being an infection of the extreme ulnar portion of the hypothenar eminence. In this case there was suppurative cubital adenitis.

Among the eleven anterior infections there are two exceptions to the rule. In six of the cases there was marked axillary adenitis with no epitrochlear swelling or tenderness.

Of the twenty-nine dorsal cases but one has proved to be an exception. It was an angry-looking paronychia, very tender and painful, but with neither cubital nor axillary involvement.

Two cases of epithelioma, one volar and one dorsal, followed the rule.

The epitrochlear adenitis does not seem to bear the slightest relation to the position of the digit involved. Thus the list is found to contain cubital enlargement in connection with infection of any one of the fingers.

[1] Read, January 9, 1894, before the New York Academy of Medicine, Surgical Section.

Name.	Age.	Date.	Region of infection. Anterior.	Posterior.	Enlarged cubital node.	Remarks.
A. Bernard	45	November 19, 189[illegible]		Contused wound of middle finger.	Present.	
Morits Zinger	39	November 22, 1892		Paronychia of thumb	Present.	
Reuben Rubinowitch	20	May 24, 1892	Volar cellulitis of middle finger.		Present.	
G. Hansen	29	May 24, 1892		Paronychia of middle finger.	Present.	
Abe Goldstein	20	May 7, 1892	Volar cellulitis of thumb		Absent	Axillary enlarged and tender.
Pincus Schalitte	17	May 5, 1892	Ulnar hypothenar, healed wound.		Present.	Suppurative.
John Friedrichs	21	April 12, 1892		Infected wound of dorsum of wrist.	Present.	
Nelly Green	17	June 28, 189[illegible]	Thenar abscess		Absent	Axillary nodes enlarged and tender.
Fred Baumbusch	18	June 28, 1892		Infected incised wound of knuckle of ring-finger.	Present.	
Harry Feem	18	December 22, 1882.	Superficial infected laceration of right index.		Absent	Axillary considerably enlarged and painful.
E. P. N., Jr.	21	January 15, 1890		Abrasion of second knuckle of right index.	Present.	Suppuration; removal of gland; sore on penis four weeks before; no secondary and no other glands, but cured by antiluetic remedies.
Patient of Dr. M. H. Richardson, Boston.	15	Summer of 1885		Large epithelioma of dorsum of left hand.	Present.	Amputation. Seen by the writer at Massachusetts General Hospital.
Dr. E. S.	25	July, 1892		Paronychia of right index	Present.	
Dr. F. E. D.	35	August, 1892		Infected contusion of left thumb, ungual region.	Present.	
Sophie Rubinowitch	34	August 13, 1892		Left thumb metacarpal	Present.	
Paula Gross	18	August 23, 1892	Deep volar cellulitis of middle finger.		Present.	Later there was necrosis of the phalanx.
Louis Rubinowitch	15	August 23, 1892	Deep thenar phlegmon		Present.	
Fromnie Liberman	33	August 30, 1892		Furuncle of hand	Present.	
Christine Andesen	30	August 30, 1892	Volar cellulitis of finger		Present.	Inflammation down to the tendons.
George Conmey	15	August 4, 1892	Palmar abscess		Absent.	
Louis Kohn	33	October 8, 1892		Furuncle of finger	Present.	
Adolph Weisenthal	36	October 15, 1892	Large hypothenar furuncle.		Absent.	
M. Flataw	36	October 29, 1892		Furuncle of middle finger.	Present.	Very much enlarged.
Tim Curran	44	October 29, 1892		Superficial infected wound of hand.	Present.	
Mike Conkling	20	November 10, 1892.		Abrasion of little finger	Present.	Node very painful and tender.
Barnard Smith	38	November 15, 1892.		Infected wound of hand	Present.	
William Hanover	17	November 17, 1892.		Dorsal pseudo-erysipelas	Present.	Later there was palmar pseudo erysipelas; gland very large.
John Banon	27	December 13, 1892.	Superficial palmar abscess.		Absent	Abscess followed infection of a callosity over root of middle finger; axillary glands enlarged and tender.
Herman Salomon	20	December 13, 1892.		Paronychia of right middle finger.	Present.	Both epitrochlears to be felt; right much larger and tender.
Jacob de Walter	23	November 15, 1892.		Paronychia	Absent.	No axillary nodes.
John Parini	21	December 12, 1892.		Dog-bite of little finger (right).	Present.	Was bitten four weeks before, but wound had broken down; cubital node greatly enlarged.
Harry Sofion	10	June 25, 1892		Infected laceration of fingers.	Present.	Suppuration, with extensive cellulitis.
Sara Zofen	55	May 7, 1892	Epithelioma of right index; ungual phalanx.		Absent.	Axillary nodes enlarged and hard. Seen by Dr. Goldenberg. Microscopic examination of tumor.
H. Bierman	36	June, 1892.		Infected incised wound over olecranon.	Present.	Cellulitis. Incision with Dr. H. Heiman.
Mary Probinko	42	December 20, 1892.		Infected "brush burn" over olecranon.	Present.	Very tender and painful.
Thomas Kane	31	December 17, 1892		Furuncle of wrist	Present.	
Max Talmage	17	July 14, 1892		Furuncle of index	Present.	
Anna Tyrol	28	July 23, 1892		Furuncle of middle finger.	Present.	Axillary enlarged.
Bernard Held	24	July 28, 1892	Cellulitis of thumb and thenar region.		Present.	Suppurative.
William Preston	17	August 11, 1892	Puncture of palm, suppurating.		Absent	Axillary enlarged and tender.
John Thorn	52	January 7, 1893		Infected wound of proximal knuckle of left middle finger.	Present.	Size of marble; no axillary glands. Seen by Ladinski, Goldenberg, et al. Shown to Surgical Section.

Anatomists vary considerably in their descriptions of the lymphatic system of the hand and forearm. In a letter by Dr. H. Goldenberg to the June, 1892, number of the *Journal of Cutaneous and Genito-Urinary Diseases*, the theory is advanced that, reasoning from Sappey's description of the lymphatics, infections of the three radial digits should skip the epitrochlear node, while infections of the two ulnar digits should cause enlargement of this body. Professor Lewin, however, believed that the superficial lymph-vessels entered the axillary nodes direct, while the deeper ones passed through the epitrochlear. Judging by my observations the latter view seems to be the correct one.

The reason for my conclusions would then be that, on the back of the fingers and hand, and over the superficial portions of the ulna, there is so little tissue between skin and bone that superficial and deep lymphatics must be influenced by nearly all infections. On the anterior surface of fingers, hand, and forearm, however, there is such a thick pad of tissue that a superficial infection may exist without involvement of the deep lymph-spaces.

Since the above paper was read, Dr. R. W. Taylor has told me of two cases of chancre of the hand, both of which were exceptions to the rule which I have deduced from my observations. One was volar, with epitrochlear nodes first involved; the other dorsal and superficial, with axillary nodes and no epitrochlear. These and similar exceptions may show that syphilis follows an erratic course as to involvement of these lymphatics, or that there may exist an undiscovered law for this class of infections.

Ferratin.—This is the name given by Professor Schmeideberg, of Strassburg, to a compound of iron which he has extracted from the liver of the hog. Ordinarily, he says, it contains six per cent. of iron. As now prepared, and to be obtained in commerce, it occurs in the form of a fine powder of a reddish-brown color, of two varieties, one of which is insoluble, and the other, combined with sodium, easily soluble in water on agitation. For the purpose of dissolving the second form of the powder the water must be as free as possible from lime, otherwise an insoluble calcium ferratin will be formed. A watery solution of the sodium compound may be added to milk or to any other liquid food, especially in the diet of little children. Either form of ferratin may be administered in the shape of powder. From a grain and a half to seven grains may be given daily to children, and from fifteen to twenty-two grains to adults. It may be given in one dose or in two or three doses. Acid articles of food should not be taken during the employment of ferratin.—*New York Medical Journal.*

Vesical pain may be a symptom of pyonephrosis.—Guyon.

ENTERECTOMY—END-TO-END ANASTOMOSIS—CHOLECYSTENTEROSTOMY WITH MURPHY'S BUTTON.[1]

By W. B. ROGERS, M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY AND CLINICAL SURGERY IN MEMPHIS HOSPITAL MEDICAL COLLEGE; CONSULTING SURGEON AND VISITING SURGEON AT ST. JOSEPH'S HOSPITAL; CHIEF SURGEON TO KANSAS CITY, MEMPHIS AND BIRMINGHAM RAILROAD, AND TO YAZOO AND MISSISSIPPI VALLEY RAILROAD; FELLOW OF SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION, ETC.

Case I. *Resection of Small Intestine for Gangrene—End-to-end Anastomosis with Murphy Button.*—Thursday, October 12, 1893, R. H——, male, twenty years of age, jumped from a wagon to the ground. The jar caused the descent of a right inguinal hernia, to which he had been subject for several years. He had theretofore been able to reduce the hernia, whenever it appeared, without the aid of a physician. On this occasion, however, he failed, and called his physician, who without the aid of an anæsthetic, and with very little effort by taxis, succeeded in pressing the hernia apparently back into the abdomen. The patient, however, continued to complain of pain extending from the inguinal canal toward the umbilicus. There was a slight fulness or induration at the site of the internal ring, but apparently within the abdominal cavity. The patient's general condition was nearly normal. During the next two days calomel, salts, and oil failed to act on the bowels. So also did repeated enemas of large quantities of water fail to bring away fecal matter. The abdomen was gradually becoming distended and tympanitic, and when I saw him, two days after the occurrence of the hernia, I found belly greatly swollen, tympanitic, with marked tenderness from the umbilicus down to the inguinal canal on the right side. He was vomiting a dirty greenish looking fluid, with distinctly fecal odor. Pulse and temperature about normal. I invaginated the scrotum with my finger, carrying it well up into the inguinal canal, but was unable to feel the hernia there, though just above Poupart's ligament, and just under the internal ring, there remained a small induration, indistinctly felt by reason of distention of the abdomen. The conclusion was that the hernia had either been reduced in its sac, or else that both had been well pressed up the inguinal canal, and between the peritoneum and wall proper. An operation was at once decided upon. An incision three inches long was made over the site of the appendix. At least a pint of blood stained water escaped from the peritoneal cavity. Inserting my two fingers I detected a constriction at the internal ring, and succeeded in drawing out eight inches of intestine. This I brought through the abdominal wound to the outer surface of the abdomen. It was so congested that at each end of the eight inches, where the encircling band had constricted it, that the peritoneum had given way and gangrene was imminent. I immediately cut out ten inches of intestine and made end-to-end approximation by means of Murphy's button. All hemorrhage was arrested, the abdomen cleansed, and drainage-tube so placed as to reach the bottom of the pelvis. The wound was closed with silk suture and the patient taken off the table with a pulse of 80. The reaction that night was pronounced, temperature reaching 103° F., but fell promptly by morning to 99½° F. His pulse from that time on did not go above 86; his temperature ranging under 100° F. Fifteen grains of calomel were given the night after the operation; ten grains were repeated the next day, and by means of oft-repeated large enemas the intestinal canal was thoroughly emptied of all gas and fecal matter at the end of sixty hours. The patient's general condition was good all of the time after the operation, and he expressed himself ready at any time to get out of bed and go to work. Thirty-two days have now elapsed and his bowels are acting every day without medicine. His appetite is good, and he is eating ordinary food. The drainage-tube was removed on the third day. The button was passed at the end of the seventh day.

The patient was then presented for examination by the fellows of the Association.

Case II. *Distended Gall bladder—Cholecystenterostomy by Murphy's Button.*—Captain L——, fifty-three years of age, of sedentary habits, and had suffered more or less with dyspepsia for years. Six months before he became very much jaundiced. The liver was greatly enlarged. He had no fever; pulse feeble at sixty beats per minute; was emaciated to almost the last degree. There was great pain over the pyloric region, with tenderness all along the liver, which projected in a uniform line three inches and a half below the border of the ribs. At the anterior axillary line there was a distinct projection downward from the liver reaching the anterior superior spinous process of the ilium. The case had been diagnosed by several physicians as cancer of the liver. While the symptoms pointed strongly to such a condition, I was not willing to consent to the diagnosis without an operation. This growth had been so rapid, had overreached the rapidity of growth so characteristic of malignancy. I detected what I thought to be the rounded end of the gall-bladder projecting at the lowest point of the enlarged liver. An incision was made two and a half inches below the anterior extremity of the ninth rib, extending downward three inches. Upon entering the abdomen I found the liver greatly enlarged and very much congested; it was blue at its surface, and projecting at its lowest point was the gall-bladder. I succeeded in bringing the fundus of the gall-bladder in the incision, and opening it evacuated fourteen ounces of bile. With a probe introduced into the gall-bladder, and my two fingers in the abdominal cavity, I was enabled to follow the cystic to the common duct, but no farther. I examined with my two fingers the under surface of the liver, and found no signs of malignant disease. I tested the common duct to the duodenum, and could find neither gall-stone nor malignant growth, but the liver was so swollen that a stone in the common duct might easily have escaped touch.

The condition of the patient at this time admonished a rapid completion of the operation, so that I did not attempt a cholecystenterostomy, but sutured the gall-bladder to the anterior wall of the abdomen, hoping that under the use of liberal douches of hot water I might succeed in clearing out the common duct. He reacted slowly after the operation, but in a few days was out of all danger. The hot-water douching was tried, and every effort made to pass a probe along the common duct without success.

At the end of three weeks he had gained some in strength, his appetite was good, and his color had nearly resumed the natural. The liver had receded beneath the ribs. In this state I allowed him to return to his home to recuperate before I operated for cholecystenterostomy.

Second Operation.—Patient returned after three weeks with general condition very little improved, but the absence of bile from his bowel seemed to have prevented his gaining in flesh. The prospect of improvement in the absence of bile was so unpromising that, although his condition was bad, in consultation it was deemed advisable to connect the gall-bladder and the bowel. At the time of this operation I again explored the tract of the common duct and felt two distinct enlargements, believed to be calculi. The case was not one to waste time in efforts at removal of calculi from the common duct, so I hastily did the cholecystenterostomy and used the Murphy button. The case progressed favorably, the button coming away from the fistula in the abdomen on the seventh day. We had much trouble in keeping the food from escaping *via* the gall-bladder. Most of the bile passed into the bowel. His condition for ten days was precarious indeed, but he slowly improved, and he went to his home at the end of four weeks. There he gained about fifteen pounds in flesh, and was slowly but

[1] Read before the Southern Surgical and Gynecological Association, New Orleans, November 15, 1893.

steadily improving until, three months after the operation, when he was taken with diarrhœa, which soon becoming dysenteric, caused death on the third day.

The operation, however, of gastroenterostomy with the Murphy button proved entirely satisfactory, and, so far as an operation was concerned, is to be regarded as a success in this case.

TWO CASES OF CHANCRE OF THE TONSIL.

By WALTER F. CHAPPELL, M.D., M.R.C.S. Eng.

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, NEW YORK (THROAT DEPARTMENT).

Mr. A——, aged thirty-two, married, consulted me on December 8, 1893, for a sore throat, of which he gave the following history: Seven weeks ago he began to have slight pain and soreness on the left side of his throat in the tonsillar region; this gave him little anxiety, as he frequently had sore throat from excessive cigarette smoking. Not improving after a week or ten days he consulted a physician, who prescribed a gargle which was used for some days without any relief. Two weeks later, while on a Western trip, he consulted another physician, and received tincture of iron and chlorate of potash to take internally and to gargle. On November 25th he returned home, feeling weak, and with considerable pain of a stinging character over the left tonsil and running into the left ear. The submaxillary gland of that side was slightly enlarged, and he felt the sore place on the tonsil with his finger, and describes it as a hard lump which seemed to pass up behind the soft palate.

On examination I found Mr. A—— looked pale, exhausted, and complaining of burning pain in the left side of pharynx and ear, especially severe at night, and accompanied by profuse perspiration, necessitating a change of night shirt. Temperature ranged from 99⅘° F., A.M., to 101° P.M., pulse 100, left tonsil moderately enlarged and very hard at its upper part. Its surface was red, and a small, superficial, grayish looking ulceration was apparent at the superior end of the tonsil; below this some grayish, sticky fluid adhered to the surface. Another small, grayish, superficial ulceration appeared on the anterior surface of the soft palate, just above the margin of the arch, and close to the uvula. The surrounding tissues were moderately red and hardened. The anterior and posterior pillars, especially the latter, were red and hard. The same condition extended to the left lateral fold of the pharynx and passed up behind the soft palate. The right tonsil and other parts of the pharynx and mouth were healthy.

There was little pain in swallowing. The left submaxillary gland was enlarged, but not tender. On questioning he admitted that about two weeks before his throat began to be sore, that "a friend" had put her tongue in his mouth a great many times while he kissed her. Some sputa and small pieces of grayish membrane taken from the ulcerated surface were referred to an expert microscopist, who reported as follows:

"Six cover-glass preparations from the well-teased specimen, double stained Nelson Ziehl method, fuchsin and methyl blue, were examined with a Zeiss apochromatic one twelfth homog. immers., and the four and five compensating eye-pieces failed to indicate the presence of any tubercle bacilli. Pieces of the membrane subjected to a special microscopic examination were found to possess the following characters:

"Fibrillar connective tissue, the greater portion consisting of intercellular substance, with isolated portions containing connective-tissue corpuscles and a few pus-cells." Dr. A. H. Smith examined the lungs and pronounced them sound. Primary chancre of the tonsil was diagnosed, and two-grain tablets of hydrargyrum cum cretâ ordered every two hours, with a soothing gargle, and a hot bath every night. Three days later Mr. A—— appeared with a macular rash on the neck, arms, chest, and back. The throat had improved in appearance, and the hardness of the tonsil and submaxillary gland much lessened.

On December 22d, fourteen days after my first examination, the sore on the tonsil and soft palate had healed, and the surrounding hardness of the tonsil and submaxillary gland nearly disappeared.

In June of this year I saw another case of chancre of the tonsil, but, with several others, did not make a diagnosis for some time after first seeing it. It was supposed to be a later manifestation of syphilis, and treated with iodide of potash without any benefit. From further information obtained regarding the man's habits, and subsequent developments, it proved to be a primary affection of both tonsils which yielded at once to mercurial treatment.

Previous to reading Dr. L. Duncan Bulkley's report in the "Transactions of the Medical Society of the State of New York," I had supposed that a primary sore on the tonsil was extremely rare. It would seem, however, that its occurrence is not at all uncommon, but may be easily overlooked.

22 East Forty-second Street.

TREATMENT OF MYOPIA WITHOUT GLASSES.

By W. H. BATES, M.D.,

NEW YORK,

ASSISTANT SURGEON NEW YORK INFIRMARY.

Acquired myopia is very prevalent. More than twenty-five per cent. of all students twenty-one years of age are myopic. Among older students the proportion of acquired myopia is more than sixty per cent. (H. Cohn, Erismann, Conrad, Reuss, Pflüger, Agnew, E. G. Loring, H. Derby, R. H. Derby, Norsa, Belt, Randall, and others).

Object of Treatment.—1. To cure functional myopia caused by spasm of the accommodation. 2. To improve the vision of axial myopia so that glasses will not be necessary.

Results of Treatment.—1. Functional myopia caused by spasm of the accommodation has been cured by treatment, and normal vision obtained without glasses. 2. The vision of a number of cases of axial myopia has been improved by treatment so that glasses were no longer necessary. 3. The eyeball has never been shortened by treatment in a single case of myopia.

The first stage of acquired myopia is usually spasm of the accommodation; tension of the ciliary muscle. The eyes are constantly focussed or accommodated for near objects, and do not relax in order to see distant objects. Concave glasses are necessary for distant vision and such eyes are practically myopic. It is only in this stage that myopia can be cured. Spasm of the accommodation may last for years, or it may, early or late, cause elongation of the eyeball, incurable axial myopia.

Glasses are often prescribed in the first stage of acquired myopia, when treatment of the spasm of accommodation by appropriate hygienic, local, or constitutional measures would have cured the near-sightedness without glasses. It is the rule that acute diseases of the lungs, stomach, and other parts of the body tend to complete recovery, and the same fact is true of the eye. Acute myopia is usually a functional disease, and glasses should never be prescribed until treatment to relieve spasm of the accommodation has failed.

Acquired myopia is often caused by the injurious effects of light on eyes which are weak from various causes. A temporary myopia from spasm of the accommodation may be produced in normal eyes by sudden exposure to strong light. Individuals whose eyes have been strained by near work suffer more from spasm of the accommodation by sudden exposure to strong light, and the poor vision lasts longer. Individuals whose eyes are weakened by constitutional debility; school children especially, who obtain little fresh air and exercise; and individuals who suffer from inflammations of the eye (conjunctivitis, keratitis, iritis, etc.), are particularly liable to develop spasm of the accommodation from the effects of strong

light. In some cases the eyes may be so sensitive that even moderate daylight or artificial light is sufficient to cause spasm of the accommodation. Astigmatism, weak interni, and opacities of the media are predisposing causes of spasm of the accommodation.

The differential diagnosis of functional myopia caused by spasm of the accommodation, and axial myopia from elongation of the eyeball, can be made in a variety of ways:

1. Atropine usually paralyzes the accommodation and relieves functional myopia. The test with atropine is by no means conclusive, because many cases of undoubted spasm of the accommodation have not been relieved by its use.

2. Rest of the eyes in a dark room for a few minutes, and later testing the vision, will show greatly improved or normal distant vision for a short time in some cases of functional myopia.

3. Some cases of spasm of the accommodation for distant vision can read diamond type (Jaeger No. 1) at a farther point than their degree of apparent myopia would allow. For example, a patient who requires a concave twenty-inch glass for distant vision has at least some spasm if able to read Jaeger No. 1 at more than twenty inches.

4 With the ophthalmoscope in spasm of the accommodation the macular region can be distinctly seen without the aid of a minus glass. In some cases the retina can always be distinctly seen. In other cases it comes and goes, or appears and disappears. In still other cases there will be days when the macula cannot be distinctly seen without a minus glass, and the patient will appear to have axial myopia, but an examination made at another time will show spasm of the accommodation.

5. Wearing convex glasses relaxes the spasm temporarily in some cases of functional myopia.

Possibilities in the Treatment of the Vision of Axial Myopia.—As a general rule the vision of the higher degrees of myopia is poor without glasses. In a myopia of 4 D. or more, the vision is usually $\frac{1}{2}\frac{0}{0}$ or less. Exceptional cases are found where the vision is unusually good without glasses, and these cases suggest the possibilities of treatment.

Dr. Seabrook, of New York, kindly furnished me with the notes of the following case of myopia: Miss T——, aged seventeen, under atropine, vision of both eyes $\frac{2}{1}\frac{0}{0}$, with -6 D. S. $\bigcirc -2$ D. C. $180° = \frac{2}{5}\frac{0}{0}$.

A very remarkable case was the following: Miss M——, aged thirty-nine, had a vision of $\frac{2}{4}\frac{0}{0}$ without glasses. She had used atropine repeatedly, and the degree of myopia found was more than 8 D. The patient had been examined by many well-known physicians in New York and elsewhere, and there was no doubt of the degree of myopia being at least 8 D. Pupils large. Some tension of the globe. With -8 D., vision was not improved. Noted that with -6 D. the vision was less than without glasses. The patient was asked to describe the difference between her vision with, and her vision without, her proper glasses. With glasses objects appeared distinct, but very small. Efforts to see distinctly with glasses caused so much pain that she was unable to wear them. Without glasses, objects could be seen and appeared much larger, but surrounded by a haze (circles of dispersion). She could recognize faces across the street, read signs, tell the time on a town-clock, and appeared to see very well for ordinary purposes. In order to see at a distance it was necessary for her to make a peculiar movement of her eyes which cannot be described. An ophthalmoscopic examination of one eye while the other eye saw well in the distance, revealed no change in the degree of myopia. The shadow test determined both eyes myopic during the time her distant vision was good. For several months her vision was $\frac{2}{4}\frac{0}{0}$, when it suddenly dropped to $\frac{1}{2}\frac{0}{0}$, after an attack of pain in both eyes. Treatment improved the vision.

A number of other cases of myopia (with good vision) have been observed where the vision was not materially improved by glasses. The fact which has suggested treatment of the vision of axial myopia without glasses is: "Cases of myopia occur in which the vision is good and in which glasses do not materially improve the vision." As a general rule, it may be stated that treatment of the vision of myopia without glasses will improve the vision to what it was previously with glasses. Spasm of the accommodation after recovery has a great tendency to relapse. H. Derby recommends such patients to visit their physician at least once a year. If they gave their eyes as much attention as some people do their teeth, many cases of acute myopia would obtain permanent relief from the use of glasses.

The vision of axial myopia improved by treatment also tends to relapse. It is necessary for such patients to avoid over-use of their eyes in order to preserve good vision. It is an unfortunate fact that myopes are more inclined to abuse their eyes than persons with normal refraction.

The Atropine Treatment.—Professor Schiess advocated early treatment of acquired myopia. He treated 101 eyes with atropine, gr. iv.–℥ j., instilled twice daily for one to nine months. "The result was a conviction that atropine was capable of bringing about a permanent improvement in a very large number of cases of myopia, and of causing the complete disappearance of this error of refraction in certain cases where it was but slightly developed." Of 101 eyes, 20 showed no myopia after atropinization, 66 showed less, and in 15 the myopia was unaltered or progressive.

H. Derby has reported good results from the use of atropine. Of 67 eyes treated, 15 showed no myopia after atropine, 45 showed less, and in 7 the myopia was unaltered or progressive. In one case a spasm of 7 D. was relieved in two weeks. In another case a spasm of 4.5 D. was relieved in two months.

In some cases atropine is not sufficient to relieve the congestion of the ciliary muscle or relax the spasm of the accommodation, just as in some cases of iritis and keratitis atropine does not readily dilate the pupil. Good results may be obtained in many of these cases of myopia by the use of hot water locally, and by the application of leeches to the temples in connection with the use of atropine. Dark glasses should be worn to protect the eyes from the strong light. As a general rule, the use of atropine is beneficial in all degrees of myopia. But some cases have been observed in which, after the use of atropine, the spasm of the accommodation was worse in functional myopia. The vision of axial myopia was lowered in some cases after atropine was used. A certain similarity has been suggested between glaucoma and myopia; and as atropine is usually harmful in glaucoma, its use may be expected to be injurious in some cases of myopia.

Treatment of the Conjunctiva.—Treatment of the myopia by local applications of astringents to the conjunctiva of the lids relieves some cases of functional myopia, has a negative effect in others, and in still other cases seems to be injurious. The indication for such treatment is found by trial with cocaine. The cocaine should be applied lightly to the conjunctiva of the upper lid, and not dropped into the eye. If the vision improves immediately, applications of nitrate of silver or other astringents to the palpebral conjunctiva will be of benefit. The applications should be made of sufficient strength to pale the mucous membrane. It is important to avoid irritating the eye by too strong solutions. No pain, smarting, or lachrymation should follow the treatment. It is better to make a number of applications of weak solutions at each sitting rather than a stronger solution used a less number of times. The vision should improve immediately after each application. After a time the use of nitrate of silver may cease to improve the vision. Solutions of copper, alum, gold, mercury, cadmium, zinc, have then been used and further improvement of the vision obtained. Later, silver improved the vision.

The degree of spasm of the accommodation and the

objective symptoms of conjunctivitis are not always in direct proportion to each other. A mild conjunctivitis may cause considerable functional myopia; the converse is also true. In some cases there was very little redness of the conjunctiva and no discharge of mucus; yet the application of astringents to the conjunctiva was followed by great improvement in the vision. In other cases where there was greater redness and swelling of the conjunctiva, with more discharge of mucus, very little improvement in the vision followed the application of astringents to the conjunctiva.

Treatment of the conjunctiva has cured functional myopia after atropine had failed to relieve. The vision of axial myopia has been decidedly improved by local applications to the conjunctiva.

Nasal Treatment.—The removal of spurs on the septum and hypertrophies of the turbinated bodies cured some cases of functional myopia by relieving the spasm of the ciliary muscle. The vision of some cases of axial myopia improved after nasal treatment, and the improvement in the vision seemed to be coincident with the lessened nasal congestion. The indication for nasal treatment was determined by the use of cocaine. When no improvement in the vision followed after the application of cocaine to the mucous membrane of the nose, the vision of a number of cases of myopia was not improved by the removal of projections of the septum, or by the removal of hypertrophies of the turbinated bodies.

When cocaine applied to a spur on the septum was followed by immediate temporary improvement in the vision, this improvement was permanent after the removal of the spur. In some cases a number of projections of the septum in contact with the turbinated bodies were removed with benefit. The naso-pharyngeal catarrh was not relieved in some cases of myopia in which the vision was improved by nasal treatment. The ages of the patients benefited varied from eighteen to thirty. All degrees of myopia were benefited.

The Pressure Bandage.—Many cases of myopia are improved by the use of the pressure bandage. The improvement in the vision is sometimes very decided. The bandage may be worn for an hour every day, or it may be worn all night. Patients have kept one eye constantly bandaged day and night for three months with benefit. Von Graefe many years ago called attention to the fact that the pressure bandage lessened intra-ocular tension, and the pressure bandage certainly lessens the tension of the eyeball in many cases of myopia. This may suggest the reason why the bandage is beneficial, etc. The bandage does not shorten the length of the eyeball.

Objections to the Pressure Bandage.—1. Some appear to be made worse immediately. The bandage produces too much irritation, the spasm is increased, the whole eye becomes congested, and the vision is decidedly lowered. 2. Conjunctivitis, usually mild, is caused in the majority of cases. 3. Photophobia, as a rule, is increased. 4. Opacity of the cornea occurs in some of the cases. The opacity is in the form of light lines crossing the cornea in all directions; it requires a strong glass on the ophthalmoscope to be seen, and is made out with difficulty by oblique illumination. The opacity disappears in a few days after leaving off the use of the bandage.

Some cases are improved by atropine up to a certain point, when the improvement in the vision stops. Nasal treatment may bring about further benefit. Treatment of the conjunctivitis and the use of the pressure bandage may produce still further improvement in the vision.

In conclusion, it may be stated positively that myopia tends to increase after it has once begun, unless efforts are made to prevent it. It is the rule that acquired myopia in its earlier stages is curable by treatment. No treatment has ever shortened the length of the eyeball.

64 East Fifty eighth Street.

A SURE SIGN FOR THE DIAGNOSIS OF SMALL EFFUSIONS IN THE PERITONEAL CAVITY.

By SALVADOR GARCIADIEGO, M.D.,

GUADALAJARA, MEX.

PRESIDENT OF THE SUPERIOR COUNCIL OF PUBLIC HEALTH; DIRECTOR OF THE ACADEMIC HOSPITAL SAN MIGUEL DE BELEN; DIRECTOR OF THE SCHOOL OF MEDICINE OF GUADALAJARA; PROFESSOR OF INTERNAL PATHOLOGY OF THE SAME; AND CORRESPONDING MEMBER OF THE ACADEMY OF MEDICINE OF MEXICO, AND SEVERAL OTHER SCIENTIFIC SOCIETIES OF THAT COUNTRY.

The reading of an article which appeared in the *Journal de Médecine et Chirurgie* of Paris, France, in which the early practice of the operation of laparotomy is recommended in the treatment of intestinal invagination and internal strangulated hernia, adducing as a sure sign of their existence the detection, by means of percussion of the lateral dependent walls of the abdomen, of a small sero-sanguineous effusion which generally accompanies the beginning of said lesions, suggested to me the idea of publishing a much surer and accurate way of detecting the presence of the fluid, which is at the same time applicable even in those cases in which the existence of extreme tympanitis would render percussion useless as a diagnostic measure.

I attribute some practical importance to the publication of this method, because in the article quoted early surgical interference is advocated as justified on the existence of the said effusion and its clinical detection; and if this symptom really is of such an important diagnostic value, it is very important the surgeons should have at their disposal various and sure means of discovering it with complete certainty.

The method I employ, and which can be appreciated by any practitioner who may wish to use it, is as follows: Placing the patient on his back on an inclined plane of 45°, the index-finger, well greased, is introduced into the rectum in order to examine the posterior peritoneal fold, in men; in women, the posterior vaginal cul-de-sac is examined.

If any effusion exists in the peritoneal cavity, no matter how small it may be, gravity will cause the liquid to descend to the most dependent parts, and in consequence of the position in which the patient is placed, it will gravitate toward the posterior part of the pelvic portion of the peritoneum. The exploring finger will clearly discover fluctuation, and to make sure that it is produced by a peritoneal effusion it will suffice to change the patient's position, while the surgeon's finger continues in contact with the postero-superior part of the rectum, and the liquid will be observed to change to the side on which the patient lies in his new position, and fluctuation immediately disappears, because the fluid which produced it has changed place and it cannot any longer be recognized by the exploring finger. If the patient is again placed in the former position, the fluctuation is at once felt by the examiner's finger, a circumstance which permits the surgeon to make sure, in the most positive and satisfactory way, of the existence of an effusion.

Practice has shown me the value, certainty, and importance of this diagnostic sign, and this is the reason why I believe it my duty to publish it, so that it can be employed by other practitioners who can judge of its merits.

In cases in which pain or any great susceptibility in the part of a patient renders the rectal or vaginal examination difficult, an anæsthetic can be used.

Traction of the Tongue in Asphyxia of the New-born.—Dr. Laborde reports sixty-four cases of successful resuscitation in asphyxia of the new-born by means of rhythmical traction of the tongue. Dr. Laborde thinks there must be something in it, but we do not agree with him. Most cases of asphyxia recover anyway by any simple measure of treatment. With collapsed lungs no method is of any use, and the same may be said when the heart is paralyzed. The old treatment for respiratory failure has proved itself useful, and we should hesitate to abandon it and begin to pull on the tongue. Professor Pinard has tried it three times unsuccessfully.

HERNIA AND ITS MECHANICAL TREATMENT.[1]

By JOHN B. WALKER, M.D.,

LECTURER ON HERNIA AT THE NEW YORK POLYCLINIC; ASSISTANT SURGEON TO THE NEW YORK CANCER HOSPITAL.

FOSTER defines a "hernia as a protrusion of a part, especially an internal organ, through an opening in one or more of the layers forming the wall of the cavity in which it is normally contained, usually the abdomen." Probably this condition is more frequent than is generally supposed. It seems much more evident when one remembers the number of different trusses which are advertised. Last year a single firm in Philadelphia made more than four hundred and fifty thousand trusses. Within a month a Hernia Specialty Company has been incorporated (with a capital stock of $500,000) to treat hernia in New York. Surgeon-General F. H. Baxter, U. S. A., stated that among 334,321 examinations for recruits, 16,900 were rejected on account of hernia. In the census of 1880, under the head of vital statistics, it is stated that among 756,893 deaths from all causes, 1 in every 600 died from hernia. Among 1,286 deaths from hernia, 141 deaths occurred in children under one year.

During the last three years twenty-one thousand different patients have applied at the London Truss Society. At the Hospital for the Ruptured and Crippled, New York City, about four thousand cases yearly apply for relief. These represent only a portion of the cases existing in New York City, for these cases are made up from the poorest of the laboring classes.

It is very difficult to estimate the real frequency of hernia among the general population, first, because there are very few places where any large number are observed; and secondly, because in these places, in the course of years, a large number of the cases are entered more than once—they lose their old cards, change their names, and are re entered. Malgaigne estimated that in France one in every thirteen males, and one in every fifty-two females was ruptured. Various authorities give different proportions, ranging from one to eight and one to sixteen, but probably the true proportion is less than three per cent.

Age.—The age at which hernia occurs most frequently is during the first ten years of life (probably from a lack of closure of the vaginal process of peritoneum which covers the spermatic cord). The period next most common is between twenty years and forty years, and the least common period is between ten years and twenty years.

Sex.—Hernia occurs about four times more frequently in males than in females, probably because the former work much harder and take more violent exercise.

Occupation.—The greater number of cases occur among the laboring class.

Predisposing Causes.—Probably a hereditary tendency exists as a factor in a number of cases, for among these a history of a rupture in a parent of the present patient can be obtained. The type of the structural weakness at the point of the hernia reappears in the infant, and under certain conditions a hernia is more apt to occur than in those more robust. In the infant, perhaps the most frequent and important factor is the undescended testis. Normally it should have descended from the abdominal cavity to its natural location at the bottom of the scrotum; the inguinal should have been closed, and the outlet through the peritoneum should have become obliterated before the time of birth, but in many cases there is some delay in the completion of this process. There may be adhesions within the abdomen, or the cord may be too short, so that the testis may enter the internal ring, pass partially through the canal, and there remain stationary for months, and sometimes for years. The internal ring is thus kept distended and open, therefore when the intra-abdominal pressure becomes intensified a portion of the intestine may enter, and we have a bubonocele—a beginning hernia. It may not advance further for some time, but generally it acts as a dilating wedge, and the ultimately increasing pressure pushes it downward and out through the external ring into the scrotum, thus producing the ordinary scrotal hernia. The other important factors in producing a hernia in the child are those which tend to increase the intra abdominal pressure, such as the prolonged straining when constipation exists; in cases of marked phimosis; whooping-cough; too tight belly-bands which direct the pressure downward toward the naturally weakest parts of the abdominal wall.

In the adult any cause which increases the intra-abdominal pressure upon the lower portions of the abdominal wall, such as the straining due to lifting very heavy articles, jumping from a carriage, accidents where one is thrown heavily, etc. In cases where the abdominal walls have been weakened by an operation, as in cœliotomy, operations for appendicitis, etc. In pregnant women as the result of over distention—twins, hydramnios, etc. Further, the violent muscular spasms at the time of confinement. Especially is this true in those cases of poorly nourished women who do not take the proper care after confinement, who begin work too early, and in those who bear children in too rapid succession.

Persons who are deficient in general strength and tone as age advances after middle life, have a tendency to increase in weight, and as their tissues become weaker and more lax, it is not uncommon for a hernia to develop.

Among the different varieties of hernia the inguinal is by far the most frequent. Among 100 men who are ruptured, 97.5 cases are inguinal and 2.5 cases are femoral. While among 100 women, 60.3 are inguinal and 39.7 are femoral. The inguinal variety occurs more often upon the right than upon the left side; the latter may be due to the fact that the right side of the pelvis is larger than the left, or that the greatest exertions are usually made on the right side. Next to the inguinal variety the umbilical is most frequent; this frequency is especially marked among children. It occurs about twice as often in females as in males.

There have been a larger number of ventral herniæ as the number of cœliotomies have increased. This may indicate that the abdominal wall is not so strong after it has been once incised.

Treatment.—The treatment of these cases may be considered either under mechanical or surgical methods. As the largest number of patients may be treated by the mechanical means, so this method will be described in this paper. During the past eighteen months the writer has seen at the Hospital for the Ruptured and Crippled about five thousand cases of hernia, the larger number occurring in working-men. The majority of these cases were reducible and could be well retained by a suitably adjusted truss.

In regard to the selection of a suitable truss, one should study each case carefully until he understands clearly what it is desired to accomplish. The chief aim is to keep a small, well-fitting pad directly over the internal ring, so as to close the mouth of the canal and thus destroy the communication with the abdominal cavity. The truss should be adjusted so as to fit perfectly the individual patient. It should lie above the glutei muscles, so that when one is walking the action will not tend to disturb the position of the truss and its pad. It should press backward and upward, but never downward upon the spine of the pubis. The tension of the spring must be tested, for it should not press too hard, only strongly enough to retain the hernia. The shape of the pad should be oval, but not too conical, otherwise it allows itself to be forced into the ring, and in time it gradually dilates the opening. Some have claimed that unless the pad had a groove on its under surface it would compress the cord and thus cause atrophy of the testis. The best authorities state that this groove is entirely unnecessary. The pads may be covered with leather or chamois skin, but in the warm weather a smoothly polished hard-wood, ivory, or rubber pad, is the least disagreeable, especially if the patient perspires freely.

[1] Read before the Harvard Medical Society of New York City, December 4, 1893.

In certain cases where the patient is so very thin that the hard pad presses upon the pubis, much relief will be found by replacing the hard pad by a water pad. Elastic trusses are not generally satisfactory, for they cannot maintain a constant, even pressure over the internal ring; sooner or later they lose their elasticity and the hernia ceases to be retained. A truss must be durable. One used for children should be impervious to moisture so that it may be easily cleaned.

"The best is that which holds the pad in position; keeps it there under all movements; counteracts any expulsive action of the hernia, and causes little if any discomfort. The lighter it is under these circumstances

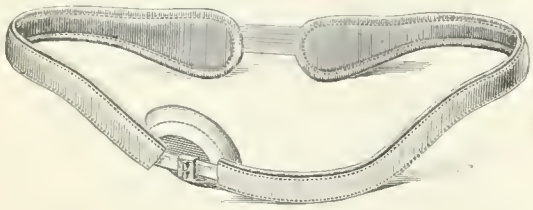

Fig. 1.

the better, and the closer it is adapted to the body the more comfort it affords."

There are three general forms of trusses which may be used in appropriately selected cases:

1. The "frame" or "hood" pattern, the best model of which is to be found in the "Pomeroy" truss. This is probably the most satisfactory variety of a truss, from the fact that it fits the pelvis so accurately and also retains the hernia so perfectly without undue pressure; firm pressure being exerted only when the hernia attempts to descend.

2. The "opposite-side" truss, so designated because it is applied from the sound side and the arm to which the pad is attached, passes across in front of the lower abdomen toward the affected side. A good truss of this variety is made by Penfield.

3. The "same-side" truss so called because it is applied from the affected side, is well represented by the well-known French truss.

In taking the measurement for a truss one should first measure the distance between the external rings, then

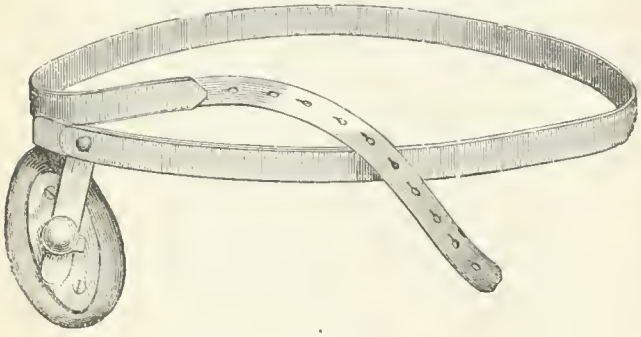

Fig. 2.

measure around the hips midway between the crest of the ilium and the trochanter major.

The cases which present themselves for trusses may be divided into the following general classes:

1. Where there is a simple bubonocele—that is, an inguinal hernia in which the hernia remains in the canal, and has not yet passed through the external ring and descended into the scrotum. Any one of the above trusses may be satisfactorily used for this class.

2. The more advanced cases, where the hernia has passed down into the scrotum, the canal has become dilated, but it retains its obliquity. Here more skill is required to select and to adjust the truss; for the opening has become larger, and it is more difficult to keep the pad in the proper place so as to retain the hernia perfectly. Truss 1 or 2 may best be used.

3. In old long-standing cases where the internal ring has been so largely dilated that the canal has become obliterated, and the hernia comes directly through the external ring. Here the opening generally admits, at least, two finger tips, and the hernia is a very large one. Thus, a much stronger spring and a larger ovoid pad will be needed. In some cases when the pad tends to slip upward and to allow the hernia to slip out underneath, it will be necessary to retain the pad in place by a perineal band passed between the legs and under the gluteal fold.

In a few special cases where the opening admits three or four fingers and the hernia has increased to the size of a child's head, no truss which can be applied will retain the hernia. A specially devised suspensory bag must be made, and these are generally quite satisfactory.

In the case of very stout patients with protuberant abdomens it is not easy, and it is oftentimes impossible, to use any other truss, except the ones figured 1 and 3.

In the femoral variety the French truss (Fig. 3) is most satisfactory in many cases. If a truss similar to Fig. 1 or Fig. 2 is used, the shank must be longer, and it must be curved more inward toward the body. It must be so adjusted as not to be moved out of position much when the leg is flexed upon the body, as in the sitting position. These cases, as a rule, are more difficult to hold than the inguinal.

In regard to children's trusses one must be very careful to see that the springs are not too stiff, for they fre-

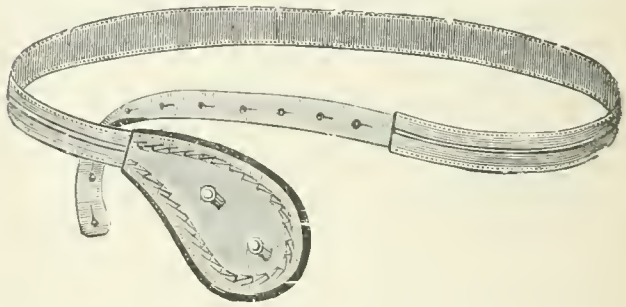

Fig. 3.

quently have this fault. They press too strongly upon the thin, tender, abdominal walls so as to pain the child. The child becomes fretful, cries, and continually disturbs the truss. He should be kept as quiet as possible, and free from all strain. In some cases, among the very thin, poorly nourished infants, it is very difficult to retain the hernia with the usual forms of trusses. Recourse may be had to the Hank truss, which is so soft that it may be very closely applied; but the general use of this truss is to be discouraged; it cannot sustain its pressure directly over the internal ring, and the hernia continually slips down.

In some cases the treatment is complicated by the presence of an undescended testis. The end to be desired is to close the ring, and to retain the testis in the scrotum. For this purpose the pad should be applied above the testis so that it will not only close the opening, but also will tend to press the testis down toward the scrotum. From time to time the parent should apply gentle traction to the testis to facilitate its descent into the scrotum. If after prolonged and thorough treatment the testis still remains in the canal and keeps the ring open, surgical measures should be considered which will fix and retain the testis in the scrotum.

It is necessary that children should be very carefully watched, and that their trusses be exchanged for larger ones as they outgrow the present one, for each truss must fit accurately if a cure is expected.

Umbilical.—In this variety in young children it is best not to depend upon the ordinary belts made for them, but to construct one as follows: A strip of adhesive plaster, two and one-half inches wide and about eighteen inches long, is laid upon the table, the child is then placed upon its back upon the middle of this plaster, the two ends are then brought forward around the child and over the pad, which is placed over the umbilicus. In

this case the pad cannot slip, whereas when the plaster is put on in front and the ends are carried backward, it will slip. The pad must not be too conical, but rather elliptical. This band must be kept firm, and it should be changed every two weeks. In favorable cases a cure may be hoped for in eighteen months.

When the umbilical hernia occurs in the adult it is best to use an abdominal belt. The belt should be made of such firm material as will not easily stretch. It should be six or eight inches wide in front, narrowing at the sides, where it is gored, to comfortably fit the patient. The pad should be slightly convex, but should not press into the ring. It should overlap the edges of the ring for about an inch on each side. A similar belt should be used in cases of ventral hernia, but a larger pad will probably be required.

It may happen in any variety of hernia, as time progresses, that the hernia slips down, adhesions form, and the hernia becomes irreducible. In an acute case no truss should be applied. If the patient comes to the clinic, a compression bandage, generally a spica, is applied, and the patient is directed to go to bed, placing himself under careful observation, so that should the hernia become strangulated it may receive immediate attention. There are, however, quite a number applying for trusses who have had a small irreducible hernia for several months, sometimes for years, without any apparent trouble. In these cases it is sometimes possible to adjust a truss with a concave pad which will just fit over the irreducible mass, and which will so compress the structures about the canal as to prevent any further increase in the hernia. In a certain number of cases the hernia later becomes reducible from being subjected to a constant even pressure, but one that is not too strong. Among two hundred and fifty eight cases which were irreducible when they applied at the London Truss Society, one hundred and fifty-six were reduced by the above treatment—fifty per cent. became reducible within three months.

Prognosis.—It has been observed by those of the largest experience that a large number of children are cured when suitable care has been taken to retain the hernia, and to keep up a continual pressure over the internal ring, thus causing adhesions between the walls of the canal. It is not infrequently the case that an adult of thirty-five or forty years of age states that he had had a rupture when an infant, that he wore a truss for a year, and was cured. The hernia had never returned until three or four days ago when he strained himself by lifting a very heavy weight, and now he has a hernia. The fact that he was free from this hernia for thirty-five or forty years would indicate that a cure had occurred in infancy. Congenital cases are much more difficult to retain, consequently the prognosis for their cure is not good. They require specially close observation, and after five years, if they are no better, the Bassini operation is recommended. In adults the prognosis for acquiring a cure by the use of a truss is unfavorable; only a few remain ultimately cured. There is a larger class who are said to be cured temporarily. The London Truss Society reports two hundred and forty cases where the hernia did not reappear for an average of 22.5 years. One hundred of these cases were in children where the hernia had occurred during the first year. In only eighteen of these cases was the patient over twenty five years of age. There were no reported cures in cases of femoral hernia. The prognosis, however, is most satisfactory and favorable for obtaining a symptomatic cure—that is, the hernia is well retained, and they are relieved of all their unpleasant symptoms. Later they are able to wear a much lighter truss.

While there is not much hope for a complete recovery in the adult, still there exists a very large class who will not submit to any operation. Indeed, few individuals after middle life expect to be cured, but these patients can be so well fitted with a satisfactory truss, that they wear them for years with great comfort and safety.

It is very necessary that they should be fitted accurately and be kept under careful observation by one who understands their infirmity and who appreciates thoroughly the dangers which may befall them if they neglect themselves. The patient should also understand the principle and purpose of the truss, and appreciate the risks which may arise if the truss fails to continually fulfil its purpose.

33 East Thirty-third Street.

Progress of Medical Science.

The Treatment of Eclampsia.—From a new study of this important subject Dr. Charpentier, of Paris, has been led to draw the following conclusions: 1. As every albuminuric pregnant woman is liable to eclampsia, and as milk diet gives such marvellous results in albuminuria, and especially in the albuminuria of pregnancy, one should examine with the greatest care the urine of all pregnant women; and if albumin be found in no matter how small a quantity, milk diet, absolute and exclusive, should be instituted at once. This is the best prophylactic treatment of eclampsia. 2. Given a case of eclampsia, if the patient is strong and vigorous and much cyanosed, begin by bleeding to the extent of 400 to 500 grams. Then administer chloral, at the same time getting the patient to begin on milk as soon as possible. 3. If the patient is delicate, and the cyanosis less marked and the attacks less frequent, the treatment should be limited to chloral. 4. Wait for labor to come on of itself, and allow it to terminate spontaneously, whenever possible. 5. Cases of tardy labor due to uterine atony should be terminated by the forceps or version, if the child be still living: or by cephalotripsy, basiotripsy, or cranioclasis, if dead. 6. Wait before any such interference until the maternal parts are in such condition that it can be done without violence, and therefore without danger to the mother, namely, until complete dilatation of the cervix. 7. Reserve induced labor for the exceptional cases in which treatment by drugs has wholly failed. 8. Cæsarean section, accouchement forcé, and above all, accouchement forcé with deep incisions of the cervix, are to be rejected absolutely.—*Archives de Tocologie.*

The Anti-toxic Function of the Liver.—The Paris correspondent of the London *Lancet* writes that those acquainted with the views propounded by Professor Bouchard will be conversant with his ideas concerning the poison-destroying properties of the liver. He and his followers attach great importance to the power of the liver-cells to nullify the effects of the toxines manufactured in the intestines. The correctness of this has been corroborated by the experiments of Schiff, Heger, Roger, and others, who found that alkaloids injected into the branches of the portal vein were much less toxic than when they were introduced into the general venous circulation. M. Pavlow has confirmed these results by a series of experiments, of which I give a *résumé*. If, by means of a ligature placed on the portal vein, the blood is compelled to deviate from the liver and pass directly into the general circulation, poisonous symptoms appear, consisting of fever and nephritis, with albuminuria. That this nephritis is not due to hypertension of the blood in the renal vessels is proved by the fact that no such kidney trouble is caused by ligature of the inferior vena cava, although this manœuvre is productive of a greater tension in the renal vessels than the operation in question. A wound artificially produced in an animal whose portal vein has been tied heals very slowly; whereas a similar wound in an animal where the inferior vena cava has been ligatured cicatrizes without difficulty. The conclusion is that, when the blood is prevented from passing through the liver toxæmia occurs, which is solely due to the fact that the liver no longer plays a protective rôle against toxines, which are being continually fabricated in the intestinal canal.

Tamponnade of the Bladder after Suprapubic Incision.—Dr. Desnos reports three cases of suprapubic incision of the bladder where tamponnade of the bladder was necessary in the after treatment. The interior of the bladder was filled with strips of iodoform gauze, one end of each being left hanging out. The upper portion of the vesical wound was closed by sutures. In one of the writer's cases this procedure was done on account of extensive tuberculous ulceration of the mucous membrane. The bladder remained open about a year, when the fistula was stitched up. The patient was freed from his disease, and remains in excellent health. In the second and third cases tamponnade was done with salol gauze on account of uncontrollable hemorrhage following extirpation of a tumor. In both patients it was successful. Tamponnade of the bladder causes no inconvenience in passing urine, for the urine flows away through the drainage-tubes, and the dressing is but little soiled. In this author's cases the first strips were removed in four to six days.—*Annales des Maladies des Organes Génito Urinaires.*

Large Doses of Bismuth in Gastric Catarrh.—Dr. Pick objects to the small quantities of bismuth usually administered. He believes that the frequent failure of the drug is due to that fact. With doses of ten to twenty grains he estimates that a certain proportion does not reach the stomach for some time, being retained in the mouth, pharynx, and œsophagus. This consideration, and the fact that bismuth is almost insoluble, and the danger of poisoning therefore very remote, led him to use, in chronic gastric catarrh, much larger doses than hitherto customary, and according to a method he has adopted for the last five years. In order to free the mucous membrane from adherent mucus, the patient takes in the morning, on an empty stomach, a teaspoonful or less of Carlsbad salt dissolved in about half a pint of warm water. Half an hour later he has a teaspoonful well heaped up of the subnitrate of bismuth administered in wafer paper—in two parts, the one after the other, as the quantity is rather large to swallow at once. The gastric region is now treated to massage for a short time, in order to bring the bismuth into as close apposition to the mucous membrane as possible, and half an hour after the dose breakfast is allowed to be taken. The diet is of course duly attended to. With this method of treatment Pick has obtained very favorable results in a large number of cases. Prominent symptoms, such as a feeling of distention, tenderness in the epigastrium, and eructations, rapidly disappear, the coated tongue becomes clean, and increased appetite is established. In slight cases this has set in within eight days; in more severe cases a course of three or four weeks is necessary. No unpleasant after-effects of any description were observed.—*Berliner klinische Wochenschrift.*

Gonorrhœa and Childbed —Dr. Kronig has studied the development of gonococci in nine women after labor. The germs are easily found in the lochia. It is certain that in women with vaginal gonorrhœa the disease may extend into the uterus during the puerperium. Gonorrhœal infection of the uterine cavity may also set up fever even when there is no trace of mixed infection, no other germs being present. Gonorrhœal infection in the puerperium is not of direct danger to life, but frequently leads to complications late in the puerperium, the disease progressing from the endometrium to the tubes. Two cases of this kind are recorded. The first, after the usual careful routine treatment, left the hospital on the fourteenth day. Two weeks later she returned. A perimetric exudation was detected to the left of the cervix. The second case was graver. On the fourteenth day the temperature rose to over 103° F., the right elbow became painful, and effusion into the extensor tendons of the right hand occurred. During the third week right parametritis set in, the temperature rising to 104° F. Then the pain and parametric swelling subsided. The fluid from the tenosynovitis was sero-purulent, but free from germs.—*Centralblatt für Gynækologie.*

Surgical Treatment of Perforating Gastric Ulcer.—Dr. Barling publishes three records of surgical intervention in perforating ulcer of the stomach. In one of these cases, notwithstanding a very unfavorable prognosis, the patient made a good recovery. For success in the operative treatment of cases of this kind, two things, it is stated, are unnecessary—early diagnosis and prompt operation following on this. The following are described as the main outlines of the operation to be performed in cases of acute peritonitis from perforation of the walls of the stomach: The abdomen should be opened in the middle line above the umbilicus, but not too near the costal margin. Positive evidence may at once be found of perforation in the presence of free gas or food. The area between the stomach and the liver should be examined with care, so that any localized collection in this region may, if possible, be prevented from soiling the more distant parts of the cavity. After the removal of extravasated matter, the perforation should be sought for. It will usually be found on the anterior wall of the organ near the lesser curvature. The perforation, if accessible, should be sutured, the sutures being applied, if possible, with the involved portion of the stomach outside the peritoneal cavity. It would be advisable, the author thinks, before doing this, to pass a piece of drainage-tube through the hole into the stomach and to draw off any fluid contained in its cavity. It is not necessary to pare the edges of the ulcer. In one of the author's cases, the only one in which the opening was closed by stitching, the edges were tough, and held the sutures well. Should the edges be found to be friable, the difficulty might be met by extensive infolding of the margins of the ulcer. Paring the edges takes time to effect, and should be avoided, as prolonged exposure of the patient militates greatly against recovery. If the ulcer cannot be closed by sutures its edges might be stitched to the lower angle of the external wound. If this cannot be done, the only resource left to the surgeon is drainage by a tube leading directly to the point of leakage. The abdominal cavity should be washed out and thoroughly flushed with hot water. A drainage-tube should be left *in situ* close to the perforation, whether this has been sutured or not. A second tube should be inserted into the abdomen just above the pubes, otherwise the drainage of the peritoneal cavity would be very imperfect, and a considerable quantity of fluid might collect in the pelvis and greatly interfere with a successful issue. In chronic cases of leakage from a gastric ulcer the author would make an incision directly into any inflammatory swelling that might exist, and, in the event of pus or other fluid being found, would remove this with the greatest care. He would refrain from washing out the abdomen, but would insert a drainage-tube into the cavity of the abscess. To search for the perforation with a view to closing it would, it is held, be useless and dangerous.—*Birmingham Medical Review.*

The Influence of Neutral Salts on Serum Alexine, Enzyme, Toxalbumine, Blood-corpuscles, and Anthrax Spores.—Writing on this subject, the Berlin correspondent of the *Medical Press* says that Professor H. Buchner found that the activity of the serum of dogs and rabbits was destroyed by the addition of water, and restored by the addition of normal neutral solution. The *rôle* of the chloride of sodium can only be indicated, as its presence alone renders the action of the serum alexine possible. Serum alexine, according to the author's terminology, being the anti-bacterial material of normal blood. Besides chloride of sodium a series of other substances can also exercise this function, such as potassium, lithium, ammonium, chlorides and sodium, potassium, ammonium, and magnesium sulphates. The saline requirements of the serum are identical with those of the whole organism. In the serum there must be an albuminous constituent which is in relation to the function of the salt; the alexines must, therefore, be considered as albuminous bodies. The presence of sulphates of the alkalies (the best is equal

parts of an eight per cent. ammonium sulphate, or 28.4 per cent. sodium sulphate solution) increases the activity of the serum alexines, and increases its power of resistance to heat about ten degrees of temperature. Sodium chloride acts also as a preservative against heat when added, but in equal quantities not so powerfully as the sulphate, and the nitrate possesses less power still. The conserving action of the saline addition depends on the relative attraction for water of the various salts, this attraction, according to Hofmeister, being strongest in the sulphates, weakest in the nitrates, while the chlorides occupy a middle place. The invertine of yeast shows a heightened resistance to ten degrees on the addition of sodium sulphate, but when the nitrate is added an only slight one on the addition of the chloride. The toxalbumin of tetanus and the bacillus of diphtheria evince a similar behavior in the presence of salt, as do also the blood corpuscles of the dog and the rabbit. The spores of anthrax are more resistant to heat in strong saline solution than in plain water. In a dried state, not only enzymes and toxalbumins, but also serum alexines, bear a materially higher temperature without losing their power. All these individual phenomena appear to the author to be comprehensible only under the assumption that plain water has an injurious action on the active albuminous bodies under investigation, on alexines, enzymes, and toxalbumins. At ordinary temperatures this injurious power comes into force only on the least resistant, the alexines and blood corpuscles, but at higher temperatures also on enzymes, toxalbumins, and anthrax spores. This injurious action is diminished by the presence of salts in the solution, while drying is another means of protecting active albuminous bodies from the injurious effects of plain water.

The Blood in Purpura Hæmorrhagica.—Dr. Denys has made observations on a fatal case of this disease occurring in a woman who was suffering for several days from some indefinite gastro-intestinal disturbance, and three days before death, without apparent cause, profuse hemorrhage took place from the vagina. Denys saw her six hours before death, and found her very anæmic, and the skin was covered with small dark-red hemorrhagic spots. Examination of blood taken from the finger-tip showed marked diminution in the number of red corpuscles and an increase of leucocytes. Peculiar small spherical bodies, like the nuclei of leucocytes, were present in considerable numbers. These showed no tendency to adhere, and were considered to be fragments of disintegrating leucocytes. No blood plaques were seen. Cultures made at the autopsy from the tissues, and hemorrhagic spots, revealed nothing that would cause a mycotic origin for the disease to be inferred.—*Indian Medical Gazette.*

Trismus Neonatorum Treated with Tetanus Antitoxin.—According to Dr. Escherich, this disease has been proved to be due to a local infection of the umbilical wound with the tetanus bacillus. But this knowledge has not hitherto yielded any therapeutic results. He reports four cases treated with Tizzoni's antitoxin. The remains of the umbilical cord fell off on the sixth, third, fourth, and fourth days, respectively. The incubation period lasted two, nine, seven, and one days, and the duration of the disease was two, five, twelve, and two days, respectively. The third case recovered, but the others died. At the autopsies septic inflammation of the umbilical wound was found in all three cases, with peritonitis in one case, and pneumonia in the other two. All the cases had septic symptoms, but it could not be positively asserted what part sepsis played in the fatal event. In cases 1 and 4 inoculation of mice with a bit of tissue taken from near the umbilicus produced typical tetanus, but in the other cases it was without result. In case 4 the disease was exceptionally acute, so that any good result could hardly be expected, and in case 1 the doses were too small. There remain cases 2 and 3, in which cure might have been expected, but in case 2 the injections were discontinued because the symptoms of septic pneumonia prevailed, and those of tetanus subsided. In case 3 the length of the incubation period and the early commencement of the disease, permitted only a fatal issue to be expected, yet this case recovered. Here one injection was given on the third day, and two similar ones on the fourth day, and a sublimate dressing was applied to the wound. In the other cases thermocautery was also used. While these results were far from satisfactory, they were nevertheless better than those obtained by other methods in this generally fatal melody. —*Wiener klinische Wochenschrift.*

The Retention of Urine after Operations.—Retention of urine is a symptom so often observed after operations that it appears strange that text books have so far paid little or no attention to the same. According to Dr. Guépin, urinary retention may occur at every age after puberty, it never has been observed before the fifteenth year. It is most frequently observed after operations upon the belly and the lower extremities, and it becomes rarer the farther away from those parts the operation took place; after operations upon the face and upper extremities it has been observed very rarely. There are two forms of retention, which differ distinctly in a clinical sense; these are the indolent and the painful forms. The former occurs in individuals with healthy urinary organs, and the latter in individuals whose urinary apparatus is diseased. The duration of retention varies a great deal. The indolent form usually disappears after the first catheterism. The second form may last from eight hours to three days, and sometimes longer. Various hypotheses have been advanced to explain the production of this kind of retention, some of them being of a rather adventurous nature. Swelling of the urethra, the dressings, pain, paresis of the abdominal muscles, anæsthesia, etc., have been made responsible for the occurrence. Guépin mentions three different causes of retention after operations: 1. Spasm of urethra, particularly of the bulbous portion. 2. Paresis of bladder. 3. Posture of patient, many persons not being able to urinate in the attitude of lying immovably upon the back. The treatment consists in change of posture and, if this is insufficient, a warm clysma, and as a last resort, catheterization.—*Medical Review.*

Relation Between the Alkalinity of the Blood and Intestinal Absorption.—Drs. Castellino and Cavazzani have sought to ascertain whether, and if so how, the process of absorption from the intestine is modified in association with altered physical and chemical conditions of the blood; secondly, they have sought to establish how such changes of the blood influence in the human subject the general metabolism of the body. (*British Medical Journal.*) The study is not as yet complete, but the authors have ascertained the following facts: In distinctly alkaline serum, the reticulum of the hyaloplasm of leucocytes undergoes stimulation, which causes increased irritability and more active vital manifestations in the protoplasm. In liquids poor in alkali the protoplasm appears torpid and slow in its reactions, but in these cases contact with alkaline serum speedily evokes increased activity. Contact of faintly alkaline serum with leucocytes, in a medium favorable to their activity, depresses their movements and accelerates the processes of degeneration. Serum which is but faintly alkaline nearly always produces transparency of the protoplasm, and throws out the nucleus. From the above facts the authors argue, first, that alkalinization of the blood favors intestinal absorption; and secondly, that as the passage of foods from the intestine through the lining mucous membrane is probably due in great measure to the activity of the cells lining the villi and to the leucocytes, alkalies would cause an increase in the rapidity of absorption by stimulating the activity of the protoplasm, and increasing its chimiotactic powers.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, January 27, 1894.

HARD TIMES AND SUICIDE.

DURING the past year the number of suicides has increased from 241 in 1892 to 313 in 1893. This is an increase of 72, or nearly one-third over the previous year. The average percentage of suicides on the population ten years ago was about twelve per 100,000. Every year from 1870 to 1880 about one hundred and fifty persons killed themselves. During the decade ending in the present year there have been, in round numbers, 2,400 suicides, or about two hundred and forty a year. Ten years ago there were just 161 suicides; hence the number has almost doubled since that time.

New York has always been something of a suicidigenous centre. The only city that has ever exceeded it in suicidal rates is San Francisco, where 7 out of every 20,000 kill themselves annually. Life seems pleasant to the Quakers, for in Philadelphia their suicides were only 8.03 per 100,000. Even the Puritan of Boston prefers to take his East wind rather than poison. Chicago people find it easier to move away than to kill themselves.

No extensive study of American suicidal statistics has been published quite recently, but so far as New York City is concerned, it looks as though Morselli's law was finding its illustration here.

"In the aggregate of the civilized states of Europe and America the frequency of suicide shows a growing and uniform increase, so that generally voluntary death since the beginning of the century has increased, and goes on increasing more rapidly than the geometrical augmentation of the population and of the general mortality."

This law is shown more strikingly in New York City by a comparison of the total mortality with the suicidal mortality. Thus, for example:

	Total mortality.	Suicides.
1883	34,011	161
1884	35,044	229
1887	38,933	235
1888	40,175	247
1889	39,679	244
1890	40,103	239
1891	43,659	300
1892	44,329	241
1893	44,370	313

Thus it will be seen that while the general mortality has increased since 1883 about one fourth, the suicidal mortality has increased nearly one-half.

Unquestionably suicide is increased somewhat by hard times, privation, and suffering, but these are not the most potent causes of fluctuations in one way or the other. Suicide depends very largely upon race and temperament. While in Central Europe 1 out of every 4,000 kills himself, in New England only 1 out of 25,000 will do it. Socquel's statistics, published in 1889, show that while insanity is the leading exciting cause of suicide, yet in these latter days drunkenness is becoming the preponderating factor. It would appear that alcohol depresses the highly organized nervous systems more than it used to do. Another fact of interest regarding modern suicide is its prevalence among the aged. While absolutely the most suicides occur between the ages of thirty-five and forty in New York, yet Thivet declares that at the age-period sixty to seventy the relative number is much greater, being 7.5 per 10,000, as against 4.7 between the fortieth and sixtieth years.

The facts above given regarding the increase of suicide in this city should be considered in connection with the anti-suicide law which was passed by the New York State Legislature. This law was an experiment, and it seems, so far as the facts can be collected, to have been a failure. It is possible that the number of unsuccessful attempts and feigned attempts at self-destruction may have been lessened, but a determination of this point would be very difficult.

On the whole, it seems that the suicidal mortality in this city has kept at about its normal, and we presume economists might say healthy, growth. For there may be good reasons advanced to support the view that suicide is a beneficent effort of nature to rid itself of the submerged and useless elements. Its special increase in 1893 is due doubtless to the hard times; but the increase is not at all proportional to the enormous increase of suffering to which New York and all other parts of the land are being subjected.

THE CITY HOSPITAL EPIDEMIC.

THE existence of small-pox at Charity, with its dozen victims, including the warden, has not occasioned more comment than has the peculiar nature of the origin of the outbreak, and the fact that the diagnosis in the first case could be overlooked, especially as it occurred in the skin department, which is in charge of an able dermatologist. So much notoriety has been given the unfortunate event, and so much uncomplimentary criticism has been poured upon the heads of those directly or indirectly concerned, that we are pleased to give the results of an investigation, which not only serve to remove unmerited reproach from the gentlemen in question, but which prove at the same time of unusual clinical interest. The report goes to show that the patient, Schmidt, a vagrant, an alcoholic, and a syphilitic, entered the hospital with a marked tubercular syphilide covering the whole body, which had existed, according to the patient's statement, for three weeks, but which from clinical appearances has been present longer. There was no fever, and no evidence of small-pox. The patient was in a low and weak state, had incontinence of urine; and for this reason it could not be collected and was not examined. There was mental hebetude and some symptoms of uræmia, and it was from the latter condition that the patient was supposed to have died about a week later. Shortly before death pus-

tules appeared upon the body, and in view of possible variola a consultation of the house-staff was held, at which it was decided that the pustules were part and parcel of the syphilitic process. One chief reason in support of this view was that the rectal temperature did not exceed 99° F.

After lying in the morgue for five days, which of itself is not an agreeable thing to contemplate, the unclaimed body was taken into the dissecting room to perform its last duties to science. And here let the sad reflection occupy us for one moment: that the schools must needs supply to their students material covered with lesions of syphilis in an infectious stage. Here, at last, the diagnosis was made. It is hardly to be supposed that this was an instance of post-mortem variola, hence the man must have had the disease at least several days before he died. A mistake had evidently been made; but was a mistake, under the conditions presented, to be looked upon as criminal, culpable, or even unpardonable? Considered in all fairness, it would seem that such an oversight might happen to even the elect. Small-pox by itself is not invariably of such pronounced type that a diagnosis, at first glance, must be made; but when small-pox and great-pox join forces to deceive, one must indeed be on the alert.

Let the lesson, with all its painful impressiveness, be learned by others as well as by those who have gone through the experience.

Although but one body can exist in one place at one time, two or more eruptive diseases can coincidently occupy the surface of the body, and one of them may be small-pox.

LIFE TENURE ON HOSPITAL BOARDS.

A CORRESPONDENT, whose letter is published elsewhere, writes us a somewhat emphatic letter concerning the burning question of hospital managers and hospital physicians. Regarding the particular case of the New York Infant Asylum, he has quite missed the point. As we are informed, the Medical Board resigned because of grossly discourteous personal treatment, and because they were refused any voice whatsoever in selecting the members of the Medical Board with whom they were to associate.

But apart from this, our correspondent raises a question which is really deserving of careful consideration. He does not believe in life-appointments to hospitals, and he thinks apparently that every man ought to have his chance. We do not think that anyone will deny that the proposition as regards life-tenure of office is a just one. On the other hand, the view that a hospital physician should have only one or two years' tenure is most fallacious. Many attending physicians and surgeons do a great deal of work, and expend a great deal of time in their hospital practice, because they hope that in future years this work, if continued, will bring them some reward. In a year or two, however, but little could be accomplished. It is too short a term to establish a reputation or win any superior skill, while the knowledge that one's place will soon be taken by another who may enjoy the fruits of work already begun, is most discouraging.

We believe that some middle ground is the safest, and would be most satisfactory.

It is curious, we would add, that no one seems to think of the advantages that might accrue from some other way of appointing and keeping up the membership of managerial boards. Most of these boards are close corporations, and their methods of self-propagation are not always wise.

THE LOCAL LESION OF SCARLET FEVER.

WHEN we have once learned surely the portals by which disease enters the human system, it becomes much easier to keep it out. Thus, it is agreed that typhoid fever and cholera can only infect through the alimentary tract, and with this knowledge everyone feels safer. It would be very comforting if we could believe that scarlet fever was introduced into the system in only one way and through only one channel. Dr. Dowson, of Bristol, has put forth a theory that this is the case, and that the channel of infection is the throat, or more particularly the tonsils.

He begins his argument by reference to the question of immunity. Scarlet fever, he says, is a disease which is always with us more or less, unlike measles, which disappears at times. This prevalence, says Dr. Dowson, suggests a process of selection, large numbers of otherwise eligible children escaping infection in spite of reiterated exposure. The prevalence of scarlet fever during the year 1892, in Bristol, was about .64 per cent., but during a severe epidemic in that town in 1863 the proportion was, as nearly as can be calculated, 4.5 per cent. It may, therefore, safely be affirmed that the incidence on the general population is under five per cent.; from which it may be inferred that the immunity against scarlet fever is great. Dr. Whitelegge gives 9.6 per cent. as the proportion of persons attacked during the age-period 0–15, and he attributes the decrease in the proportion after that age to "greater insusceptibility."

As a matter of fact, scarlet fever all but disappears after the age of fifteen, the returns of the fever hospitals showing less than two per cent. Not only, therefore, is the natural immunity very great, but an acquired immunity seems to come into play after the age of fifteen, which is not due to a previous attack or to diminished exposure. Dr. Dowson endeavors to explain this immunity by proceeding on the following premises, viz: 1, That the primary local lesion of scarlet fever is in the tonsils; 2, that this disease is a local disease of these parts and associated lymphatic glands, the general symptoms being caused by the absorption of toxins produced by the microbial growth at the seat of the local lesion; 3, that the incidence of the disease and the subsequent immunity are related to the structure and life-history of the tonsils.

Dr. Dowson points out that the throat affection of scarlet fever is a destructive inflammation which is always present in a more or less marked degree. His hypothesis requires that the throat lesion should be always present; that it should be among the first observable signs: that the disease should not occur apart from it; and finally, that a difference in severity of the disease should be accompanied by a proportional difference in the extent of the local lesion. The throat lesion of scarlet fever ranks among those which permanently damage the tonsils. Dr. Dowson made some five hundred observations on this point, which convinced him that after the age of fifteen there is an increasing number of patients with atrophic tonsils.

If the throat is the seat of the primary lesion in scarlet fever, it follows that the condition of these organs at different age-periods would exercise some controlling influence upon the incidence, and perhaps the severity, of the disease. The atrophy following destructive inflammation of the tonsils, for instance, would reduce the risk of inoculation and afford a less suitable nidus for microbial invasion. Out of a total of 508 observations there were only 7 instances of normal tonsils after the age of thirty; 115 persons in all possessed normal tonsils. This gives twenty-two per cent. for all ages, 21 of which occurred in the period of 0–30. Of these 115 persons, 89 had not suffered from scarlet fever, 10 had, and 16 were uncertain. Reckoning one-half of these last cases as affirmative and half as negative, we get the numbers 97 and 18, according to which eighty-four per cent. of those who have normal tonsils have not been affected with scarlet fever.

Dr. Dowson's argument is ingenious and based on a good deal of study and observation. We wish we could believe it even true, for then by destroying or disinfecting the tonsils scarlet fever could be prevented. It is difficult to understand, however, how the epidermis becomes so persistently infectious if the disease is located in the tonsils. Dr. Dowson suggests that the expired air infects the skin. A more reasonable theory would be that the system, becoming infected by the throat, throws off the poison by the skin.

LIGHT ON THE SMALL POX QUESTION.

One is brought back to the days of blue glass as a cure for consumption, by reading the accounts which come to us of the good effects of red light upon the course of variola. The combined testimony of Svendsen, Finsen, Lindholm, and others, goes to show that when the chemical rays are excluded from the light which surrounds the small-pox patient, suppurative fever does not occur, œdema rapidly disappears, suppuration of the individual lesions does not take place, but instead the vesicles dry up quickly, and all is well. Truly a rosy picture. It is recalled by Hogner, writing in the *Boston Medical and Surgical Journal*, that as early as 1300 this treatment was in vogue, and that the sickbed was covered and surrounded with red hangings to drive away the disease. The revival of this so long dead and so nearly forgotten empiricism is vested with a scientific explanation which does not seem wholly to explain. It has been shown that the sun, as well as the arc electric light, have the power to produce skin irritation, which is due to the chemical rays alone. Now, just as a photographer shuts off these rays from his dark room by the interposition of a red pane, so can a lady who is susceptible to eczema solare, go in the sun with impunity by wearing a red veil. If by red glass windows you shut off the ultra-violet rays from a face covered with the early lesions of variola, it is claimed that the skin irritation which favors the development of micro-organisms is prevented and pustules do not form. On the other hand, it has been claimed that the chemical rays of light are the most active in the destruction of bacteria, and it would seem that what would be gained on the one side by shutting them out would be lost on the other. However, when we read of twenty cases treated after this method by one observer, ten of them being in children who had not been vaccinated, and are told that all made rapid recoveries without passing into the pustular or suppurative stage, we are warranted in looking into the matter. Let us have all the light possible thrown upon the disease, and at any rate a little that is red can do no harm.

THE DEFECT IN THE DENTIST.

The dentists of America are the best in the world, but they are, nevertheless, away behind the mark. We appreciate their ingenuity, their skill, their drills and dams, their composite fillings and artificial teeth. They make the best kind of golden crowns, but they do not deserve to wear them. This is because they do not sterilize themselves or teach their patients how to prevent caries. They are wonderful patchers-up of things half gone; but they do not show us how to prevent the going.

There is hardly a dentist (there are a few) who works in an aseptic way or uses aseptic instruments. Some do not know any better, some do not think it necessary. But both are wrong; the one class should learn, the other class should think. How many dentists can tell surely when they are dealing with a syphilitic mouth? Yet if such a mouth is being treated we do not believe that any one would like to be the next patient, though the dentist should first wash his hands.

The mouth is a rich culture-ground for microbes; and caries, it is taught, is a microbic disease. Yet the dentist is content to fill the teeth, then disburse a bottle of his own special mixture of chalk, orris, and wintergreen, and tell his patient to brush the teeth *bis die*. The ordinary tooth-brushing is entirely ineffective in preventing caries or disinfecting the mouth. For this purpose a genuinely antiseptic wash is needed, and this should be used for a considerable time. Just what this wash or powder should be, and just how long it should be used, is one of the things the dentist should find out. Let the American dentist devise a way of making the teeth and gums aseptic and preventing caries. He will then be greater than if he had invented a new filling or a novel drill, or transplanted a whole jawful of teeth.

The Growing Popularity of Ether Anæsthesia in London.—*The Medical Press and Circular* has had a series of reports on the anæsthetic procedures in several hospitals of London. King's College Hospital and the Royal Free Hospital are not free users of ether; the former relies on chloroform in a majority of cases, while the latter is partial to the A. C. E. mixture. In the case of nine other hospitals, the anæsthetists administer ether in the larger proportion of cases. At the London Hospital a very notable change has taken place in this regard; ether is the anæsthetic chiefly used, being administered twice as frequently as chloroform. A few years ago the opposite preference ruled, but a careful and extensive study of the relative workings of the two substances has effected this reversal.—*The New York Medical Journal.*

Fainting.—As a rapidly acting stimulant give alcohol, hot and concentrated. The hot alcohol acts much more quickly than cold, because before it could be absorbed it must be heated up to the temperature of the body.—Hare.

News of the Week.

A College President and Football.—President Patton, of Princeton College, N. J., is reported to have said at a recent meeting of the Presbyterian Union, that "he considered football as one of the greatest moralizing forces in the college, and also that if he were a college man and had the proper physique he would try for a place in the College Eleven." The recent successes of Princeton have evidently been upsetting the worthy President, so that his feet are where his head should be. He evidently believes that the moralizing influences should come from below, instead of above, the belt. In olden times the cultivation of the upper end of the body was considered the most important, but in the new order of things we must commence at the feet and work up. Even a half-back gets more applause than a whole head.

Syracuse Academy of Medicine.—The profession in Syracuse, N. Y., have just completed the reorganization of their old City Association, calling the new society the Syracuse Academy of Medicine. They have obtained permanent quarters in the centre of the city, and have furnished the rooms handsomely for the purposes of reading-room, library, and assembly. A bequest of the late Dr. Shipman, of $500, to be invested in books, will be the nucleus of what is expected to be a good and growing library. The Academy starts out with over one hundred charter members, and the membership is expected to increase to include all eligible men in the city. Regular meetings will be held on the first and third Tuesday evenings of each month. The following officers have been elected for the first year: *President*, Dr. H. D. Didama; *Vice-Presidents*, Drs. John Van Duyn and Alfred Mercer; *Secretary*, Dr. T. H. Halsted; *Treasurer*, Dr. E. L. Mooney; *Members of Council*, Drs. N. P. Warner and Eli Van de Warker; *Trustees*, Drs. J. L. Heffron, H. L. Elsner, D. H. Murray, R. C. McLennan, and F. H. Stephenson.

Medico-Chirurgical College.—The Faculty of the Medico-Chirurgical College of Philadelphia has created three new clinical chairs, viz., Genito urinary Surgery, Orthopedic Surgery, and Otology. These, together with the vacancy in the chair of Clinical Medicine, will be filled permanently at the end of the present session.

Dr. William Hunt, Senior Surgeon to Pennsylvania Hospital, has resigned after a service of thirty years.

Dr. James Tyson has been appointed on the Visiting Staff of the Philadelphia Hospital.

The Cholera.—According to the latest intelligence, says *The Lancet* of January 13th, it appears that there is very little cholera in Constantinople at the present time. The epidemic at Teneriffe is entirely at an end, no cases having occurred since December 22d. We learn from India that one of those sudden and severe outbreaks of cholera on a limited scale, so frequently met with in India, has occurred at Nowapara, on the Eastern Bengal State Railway. The cholera epidemic continues in St. Petersburg, the number of patients under treatment for cholera in the Russian capital having risen in less than three weeks from 15 to 166. The increase has been very steady between the dates of December 12th and 27th, the statistics showing an increase of exactly 100 cases under treatment. From noon of December 12th to noon of December 13th there were 16 new cases, 5 deaths, and 66 under treatment. On the 28th there were 21 new cases, 14 deaths, and 166 cases under treatment. This sudden revival in the activity of the cholera epidemic has not yet been fully accounted for, but it has been considered possible that it is associated with the increased consumption of salt-fish taking place in connection with the Christmas fast (Rvjdestvenski), which commences at the end of November. A commission of physicians does not, however, endorse this view.

The Hospitals on Blackwell's Island.—We understand that the Medical Boards of the Workhouse and Almshouse Hospitals have asked that an investigation be made into their condition. They assert that the accommodations are insufficient and that no opportunities for efficient quarantine exist.

Chemistry and Reading Notices.—Our esteemed contemporary *The Lancet* has started a department of Analytical Records, which to Americans who are supposed not to have a very keen medico-ethical sense seems very strange. It has equipped a laboratory, and everything is grist to the scientific mill therein. We find *The Lancet* publishing analyses of champagne, lager-beer, bon-bons, cigarettes, malt, wine, tea, gin, etc. Curiously enough everything analyzed and reported upon is found to be good; so that the state of mind of *The Lancet's* chemist is very suggestive of that described in Genesis at the end of creative work.

The Local and Tonsillar Origin of Scarlet Fever.—We have called attention in another column to the views of an English physician who claims that all scarlatina originates primarily in the tonsils, which is the point of infection. Dr. Bergé, of Paris, has independently arrived at a somewhat similar view. He states that it is useless any longer to search for a new microbe as the cause of this disease, and that scarlatina is primarily a local disease, with secondary infections (the eruption, etc.) due to the formation and absorption of toxines; the pathogenic agent is the streptococcus pyogenes, the microbe of erysipelas, of puerperal septicæmia, etc. In common or tonsillar scarlatina the streptococcus finds a rich culture-field in the crypts of the tonsil and there secretes (in all probability) "an erythematogenous toxine," whose diffusion throughout the organism produces the cutaneous or mucous eruption. Bergé remarks that the tonsillar affection takes precedence in order of time, and that while the microscope invariably reveals the presence of the streptococcus in the tonsillar crypts, bacteriologists have never found microbes in the cutaneous exanthem, even by the recent methods of research formulated by Nicole.

The International Medical Congress at Rome.—The Committee has opened at Rome a special office to provide lodgings for Congress members at hotels and private houses. Members can apply also on the same purpose to Messrs. Thomas Cook & Son, Piazza Martiri, Rome, who have been requested by the Executive Committee to satisfy such applications when made in time. Excursions will be arranged in Rome under the guidance of Professor Forbes. Congress members intending to see Naples and Sicily can travel from Rome to Naples with fifty per cent. reduction on the usual railway fares, and can join

the excursions which will be arranged by the Naples Agency of Messrs. Thomas Cook & Son. This agency will arrange an undetermined number of excursions to Pompeii, Vesuvius, Capri, Sorrento, Castellamare, and Baiæ. and three to Sicily with the following itinerary: Naples, Messina, Catania, Faormina, Girgenti, Syracuse, and Palermo.

The Number of Medical Women in Great Britain is now 186, and of these 20 have become members of the British Medical Association.

The New York State Board of Health.—At a meeting of this Board, held last July, Dr. Donohue was empowered to make a thorough investigation of the office, which was to include every department and every official connected with it, down to the minutest detail of administration. Dr. Donohue's report was submitted on January 16th. It is an exhaustive document, and recommends many radical changes in the working of the department. Owing to the fact that the five new members of the board are not yet thoroughly conversant with their duties, it was deemed advisable to postpone decisive action until the next meeting, which will be held February 9th. By this time it is expected that the new members will have become acquainted with the workings of the office, and will be able to pass intelligently upon the reforms suggested in the report.

Tuberculin as a Test for Tuberculosis in Cattle.—Some veterinarians assert that tuberculin offers a sure test for the presence of tuberculosis in cattle. It is not considered to have such a positive effect upon man, and Dr. Klein's explanation of it is this: He believes that tuberculin does not act specifically on tuberculous tissues, but that it causes an increase in the power of exciting inflammation and suppuration possessed by streptococci and staphylococci. These micro-organisms are present in the majority of cases of tuberculous disease. The tuberculin increases their potency, so exciting local inflammation and producing a general reaction fever. Experience has shown that a certain number of cases of tuberculous disease do not give any reaction with tuberculin, and in Dr. Klein's opinion these are cases in which the tuberculous condition is uncomplicated by the presence of other micro-organisms.

Our French Brethren are word-mad. Hardly a month passes that some new creation of their onomatogenetic activity does not appear, and claim the attention of clinicians. Not long ago the offence of "astasia-abasia" was committed, and now Professor Debove describes a disease which he calls "basophobia," which means about the same thing, and of which there is just about as much need. There should be a society for asphyxiation of unnecessary terms.

Wharf Doctors and Runners.—The *Medical Standard* is informed that in New York the so called "wharf doctors" employ "runners" when a ship comes into port whose crew were shipped abroad; whoever hires them is responsible for their medical care when sick. The "wharf doctor," for a fixed price, guarantees medical charge of the crew while in port. If the sailors fall ill they treat them on board, while the vessel lies at her dock or is anchored in the bay. If the sailor requires attention which cannot be given on shipboard the "wharf doctor" sends him to a hospital and pays the charges. It is by these "wharf doctors" that the runners are employed. The moment a ship comes in they swarm out to her on tugs and rowboats, like so many sailor boarding-house touts, and endeavor to strike a bargain with the captain. [What next shall we learn from Chicago?]

Medical Legislation in Virginia.—The law regulating the Medical Examining Board of Virginia is eight years old. Much good has been accomplished for the protection of the public, but the organization of the Board is such that it has failed in some of its legal aspects. The *Maryland Medical Journal*, December 23, 1893, states that it is proposed to reduce the number of its membership to ten, taking one regular physician from each Congressional district, plus two irregulars or homœopaths, to be selected by the Governor of the State. It is also proposed to amend the laws governing the prosecution of itinerant quackery. The *Journal* instances a case wherein the present laws failed of the purpose during the past year: a notorious quack from one of the Northern cities set up his stand in Richmond and successfully defied prosecution, gaining his point by pleading the unconstitutionality of the license law. Under a legal technicality, and with the aid of a shrewd lawyer, the quack continued to practise at his own option and pleasure without a license from the Board of Examiners. When a lawyer goes to work to unravel the work of another lawyer, and succeeds in his endeavor, it behooves the Board to change its legal advisers, or take lessons from the counsellor who drove them out of court. Although the existing laws have been a decided benefit to the profession of Virginia, and *pari passu* have been a protection to the general public, those laws should be so strengthened that they can withstand the first serious opposition that shall be made to them. The effect, upon certain low graded medical colleges, of repeated rejections, by the Board, of their young graduates, has been to raise the standard of requirements in those colleges. One member of the faculty of a distant college is reported to have said that his college had been forced to raise the tests of graduation for the reason that his faculty was tired of seeing their graduates rejected by the Virginia Board of Examiners.

The Columbian Dispensary, of Brooklyn.—A new charitable undertaking has been begun at No. 140 Clermont Avenue, Brooklyn, in a dense population poorly provided as to medical attendance. Dr. George R. Kuhn is the leader in the attempt, but he has the support of the clergy in his vicinity. The following physicians will give their assistance to the dispensary: Dr. D. E. Callaghan, Dr. A. F. Carroll, Dr. P. J. Curran, and Dr. James F. Gallagher. It is designed to make the institution strictly unsectarian.

The British Medical Association has now a membership of 14,703.

Dr. William N. Hubbard has been elected a member of the Medical Board of the New England Society, in the City of New York.

Medical Society of the State of New York.—The railroads will charge a fare and one-third to delegates to and from Albany, where this Society meets on February 6th, 7th, and 8th. The New York City delegates will take a special train, leaving Grand Central Depot at 3.30 P.M., February 5th. Dr. Dallas, 65 West Thirty-sixth Street, Secretary of delegation.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON LARYNGOLOGY AND RHINOLOGY.

Stated Meeting, December 27, 1893.

CHARLES H. KNIGHT, M.D., CHAIRMAN.

Modified Illuminator.—DR. FELIX COHN presented a modification of Dr. Kuttneiss's electric head illuminator, the modification being an attachment for transillumination, enabling the instrument to be used either as an illuminator or transilluminator.

Modified Microphonograph.—DR. J. MOUNT BLEYER exhibited the head attachment of the microphonograph for increasing normal or abnormal sounds—musical or other kinds.

Electric Cabinet.—DR. BLEYER also exhibited an electric cabinet which contained an interrupter making 100,000 interruptions per minute for the use of electro-vibratory action upon the turbinated tissue.

Case of Sarcoma of the Nose and one of Epithelioma of the Larynx.—DR. HORACE CLARK, of Buffalo, sent the history of a case of melanotic sarcoma of the nose, for which he had operated, and also one of epithelioma of the larynx, with rapid metastasis to the œsophagus and pharynx, with death.

Laryngectomy for Epithelioma of the Larynx.—DR. HUBBARD showed an epitheliomatous tumor of the larynx for which laryngectomy had been performed the previous week. The man had since done well Preliminary low tracheotomy was performed. The enlarged submaxillary gland was excised, as well as the entire larynx, from the cricoid to the os hyoides.

Carcinoma of the Larynx.—DR. W. H. PARK presented a man with carcinoma of the larynx, who gave a history of three years' gradually increasing hoarseness and difficulty in breathing. There was no specific history. A tracheotomy tube had been inserted.

DR ROBERT C. MYLES also presented a patient with a tumor of the larynx, probable epithelioma, which had been growing gradually until the larynx was almost occluded. The question of choice of operation was raised.

DR. PARK then presented a second patient, a man of middle age, who four months before had first noticed a hard nodule in the middle of the hard palate. It had increased until it involved an area more than an inch in diameter. The diagnosis lay between specific tumor and epithelioma or carcinoma. There was no history of specific disease.

The Treatment of Follicular Pharyngitis.—DR. EMIL MAYER, in a paper upon this subject, gave a brief review of the treatment of follicular pharyngitis as practised by different specialists, some of whom had given preference to one kind or other of escharotics, some to cutting forceps, etc., and finally came down to the galvano-cautery which he had himself used and recommended, until the introduction of the Gottstein curette. It was a modification of this curette, to better adapt it to the pharyngeal surface, which had given him the greatest degree of satisfaction in the treatment of these cases. The author presented his modified Gottstein curette and gave a *résumé* of cases treated, numbering perhaps forty. In all where there was no complication recovery had been rapid. He completed the operation at one sitting, curetting the entire pharyngeal wall, or as much of it as was covered by the follicles, not touching the healthy mucous membrane. With the modified instrument there was no danger, he said, to healthy tissues. Cicatrization did not occur.

DR. MORRIS J. ASCH said he had seen many of the cases treated at the hospital by Dr. Mayer and could testify to the good results. The cure had been much more rapid than by other methods.

DR. W. C. PHILLIPS said the old Gottstein curette had answered the purpose very well, but he thought the modification shown would make it easier to handle.

The Bacteria Present in the Human Throat and their Relation to Acute Throat Inflammations.—DR. W. H. PARK read the paper. He would limit his remarks chiefly to streptococci, as they were most abundant, especially in acute inflammations. They were round bacteria, about one-eighth of the diameter of red blood-cells. They divided in one direction only, and as they divided they clung together, forming a chain. Different varieties of streptococci clung together with varying degrees of tenacity, and divisions had been made according to whether they were seen in long or short chains, and upon other grounds. Some were found to be much more virulent than others when injected into animals, some pathogenic, others not, and even those which were pathogenic at one time might not be at another.

Dr. Park, in the month of March of the current year, had made cultures from the throats of forty students and twelve other adults, none of whom were suffering, as far as known, from acute or subacute inflammation; and in the summer months cultures were made from twenty other students. In all the cases streptococci were found, in some the number and variety being much greater than in others. Similar observations were made in the country, and there also the cultures showed streptococci, so that their presence was not due to city surroundings. In the case of the country family no staphylococci were found, but these were present in most of the city cases. The throats of children in an asylum were then examined, and streptococci were found at all ages, except before the second day. In children with pneumonia and phthisis the streptococci, and also the staphylococci, were more abundant, but they seemed similar to those found in healthy throats. In scarlet fever the streptococci in the throat were also much more abundant than in health; so also in pseudo-diphtheria.

Persuaded by his observations that in healthy throats streptococci were probably harmless, he tried experiments upon himself and found that cultures transplanted to his own throat produced at most slight irritation. This was true when the cultures were from healthy throats, and also from throats the seat of acute inflammation.

The bacteria which were harmless under ordinary conditions, became more active under certain states of the weather, and were present in greater numbers during the damp winter months.

Effect of Mild Antiseptics.—Dr. Park had further observed that during the use of mild antiseptics in the nose and pharynx the streptococci became less numerous, and indeed the spray had rendered the throat almost free from pathogenic germs. This observation showed the desirability of observing local antisepsis when one was brought in contact with contagious diseases.

It was difficult to say what proportion of cases of angina, etc., developed from infection obtained from others, and what proportion from increased activity of the germs present in one's own throat brought about by changes in the weather and other causes. The author's opinion was that only a small number of cases arose from infection from others, and in those cases there was also probably some other form of exposure. The bacteria mentioned, when found in healthy localities, were less active than when they came from surgical wounds, yet they were capable of producing abscesses when injected into animals.

DR. VANDERPOEL inquired whether non-diphtheritic sore throat was not contagious, or how would the author explain its frequent occurrence in several members of a family.

DR. PARK said it was not contagious like diphtheria: it did not spread in a neighborhood from a given centre. In the same family there might be different cases, but probably due to the same general condition, say that of the weather, causing throat irritation and favoring increased activity of the germs present.

DR. CHAPPELL said that at the hospital at Forty-second Street they had concluded that follicular tonsillitis was

contagious. Formerly when a case developed the disease was apt to pass through the entire hospital, affecting all the children. The last two years they had made it a custom to at once isolate every case, and as a result the disease had not spread to the other inmates.

After some further discussion, during which opinions were expressed as to the infectiousness of follicular tonsillitis, the Section proceeded to the transaction of business.

Officers Elected: Dr. D. Bryson Delavan was elected Chairman for the ensuing year, and Dr. James E. Newcomb Secretary.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 22, 1893.

H. P. Loomis, M.D., President, in the Chair.

Ciliated Infusoria from the Urethra.—Dr. F. Tilden Brown exhibited some ciliated infusoria which he had found in the urine of a man suffering from pyelitis. When the patient first came to him he had hæmaturia, and a cystitis, which rapidly subsided. At the commencement of the treatment slides were prepared and examined for gonococci and tubercle bacilli, and these showed the infusoria; hence they were present at the time the patient came under treatment. It is probable that the free secretion of pus and the alkalinity of the urine rendered the urethra a suitable habitat for the infusoria, for they speedily die in normal urine; in fact, they seemed to thrive chiefly in physiological salt solution and in ordinary Croton water. He had, however, found them alive in this patient's urine as long as ten days after the urine was voided. At first he suspected that the infusoria came from the urinal, or from the bottle containing the urine, but he had had the patient pass some urine directly into sterilized flasks, and even then an examination made within one hour showed the presence of these infusoria. As they were not found in the urine drawn from the bladder by catheter, it would seem that they existed only in the urethra. There was no discharge from the meatus, but there was considerable muco-pus in the canal, and many shreds were found in the specimens of the urine containing the infusoria.

Eggs of the Distoma Hæmatobium.—Dr. Brown then exhibited, under the microscope, the eggs of the distoma hæmatobium found in sections from a bladder tumor. The case occurred recently in the service of Dr. B. Farquhar Curtis, at St. Luke's Hospital.

A Calculus Containing Tubercle Bacilli.—Dr. Brown also presented a small calculus which he thought was probably of renal origin. The patient was known to have tubercular disease of the urinary tract. Specimens of urine were examined from time to time for tubercle bacilli, but none found. Finally, about two or three hundred minute, soft calculi were voided, and on crushing one of these and mounting it in blood-serum, the tubercle bacilli were found in large numbers. He had not before seen any mention of this. The composition of the calculus had not yet been determined, but it appeared to be phosphatic.

Retention Cysts of the Kidney Due to Occlusion of the Ureter by a Calculus.—Dr. George C. Freeborn presented a cystic kidney which had been found at a post-mortem examination. So far as could be learned there had been no symptoms during life referable to this condition. The kidney was enormously enlarged, and was converted into a mass of thin-walled cysts, the walls of which were composed of fibrous tissue. Examination of various portions showed an entire absence of kidney tissue. The cysts contained a clear yellowish fluid which was drawn off by a series of small punctures. The cysts were then filled with chromic acid solution, and after hardening were preserved in alcohol. This original method of preparation had been described to the Society on a previous occasion.

A Cyst of the Broad Ligament.—Dr. Freeborn said that this specimen was removed by laparotomy from a married woman, twenty-three years of age, who was in the third month of pregnancy. The cyst contained 250 c.c. of perfectly limpid fluid. The operation was performed on November 15th, and the patient had done exceedingly well, and had not aborted.

Dr. Byron said that this method of preparing cysts was far superior to any other with which he was familiar. He would look upon the cystic kidney as more probably of congenital origin, for when not congenital there are usually only one or two cysts.

Dr. Freeborn said that he had considered the specimen one of congenital malformation of the kidney until he found the large calculus which had occluded the ureter.

Dr. Brown asked if the method of preparing the cysts just described and recommended was applicable to specimens in which the contained fluid was quite thick.

Dr. Freeborn replied that he had been able to almost completely evacuate the colloid material of ovarian cystomata by using a large glass or metal cannula. The chromic acid solution was then injected through the same cannula.

Preserving the Natural Blood-color in Specimens.—Dr. Freeborn called attention to the fact that in the last specimen of cyst the color of the blood had been retained in the vessels. Many methods had been devised and had proved unsatisfactory. It had been found, however, that the blood-coloring could be retained by first drying the specimen in the air for an hour or an hour and a half, and then immersing directly in strong alcohol. If put in fifty to sixty per cent. alcohol, the color will be destroyed. The same method can be used with solid organs, but as they cannot be so thoroughly dried as cysts the results are inferior.

Cysts of the Brain.—Dr. E. D. Fisher presented a brain, removed from a patient forty years of age, who died of exhaustion after a series of about sixty epileptic seizures occurring within twenty-four hours. There was a history of imbecility associated with epileptic seizures and marked hemiplegia, with contractures on the hemiplegic side. Two large, well-defined cysts were found in the motor area of the left hemisphere of the brain, extending back into the occipital lobe, and the more posterior cyst was in communication with the lateral ventricle. The difference in the size of the two hemispheres was very apparent, but the opposite hemisphere of the cerebellum was not atrophied. It was not possible, of course, to decide, so long after the occurrence of the lesion, whether the condition found in the specimen was the result of occlusion of a vessel occurring in utero or shortly after birth, or whether it was due to hemorrhage. The specimen showed very clearly the futility of operating on such cases. He had ventured to operate on a similar case, where the man had a history of having had cerebral hemiplegia develop at the age of five years, and where it seemed possible that there might be a meningeal hemorrhage. Instead of this he found a cyst very similar to the one shown in this specimen. The cyst was drained, but the operation seemed to neither benefit nor hurt the patient.

The Lesions of Yellow Fever.—Dr. J. M. Byron presented specimens from a man dying of yellow fever. While coming from Havana about three weeks ago he was taken ill on the steamer, and on reaching this harbor was put on one of the quarantine islands. When seen by the speaker he presented most of the symptoms of yellow fever—moderate yellow color, nausea, pain in the epigastrium, subsultus, and continued high temperature. The patient was twenty-four years of age, and his previous health had been apparently good.

The liver presented at autopsy the appearance more commonly seen in the early stage of the disease, when the degeneration of the liver cells is going on in the outer portion of the acini. The bladder, stomach, and intestines showed extensive hemorrhages. The kidneys were of special interest, because it had been recently claimed

that cholera could be recognized by the lesions found here. The specimen presented a very similar appearance to that found in cholera, and the microscopical appearances were identical in the two diseases, even the collecting tubes being involved in the necrosis.

Specimens from cases of cholera and yellow fever were exhibited under the microscope.

Dr. Armstrong asked what was the condition of the heart.

Dr. Byron replied that it presented, along with the other organs, a condition of fatty degeneration.

Dr. Armstrong said he would lay more stress on this than on the appearance of the liver or kidneys, for they present no characteristic features; it is the association of the pathological condition in several organs, rather than the appearance of any single organ, which justifies a diagnosis of yellow fever.

Dr. George Biggs asked if yellow fever could be positively differentiated at autopsy from a purpuric condition. He had recently made an autopsy on a case presenting quite similar lesions, yet the patient had been for a long time in the New York Hospital, and had presented the symptoms of acute purpura hæmorrhagica without skin eruption. There was a distinct jaundiced condition and parenchymatous changes in the organs, with a few hemorrhages in the kidneys.

The President thought the parenchymatous changes would furnish the basis for a differential diagnosis.

Dr. Byron said that in yellow fever the clinical symptoms must be taken into consideration along with the results of the autopsy. In yellow fever there are very extensive hemorrhages of all the mucous membranes, while minute hemorrhages are very rare; in yellow fever there is fatty degeneration of almost all the parenchymatous organs, while in purpura hæmorrhagica these changes were not nearly so extensive.

Culture Medium for the Gonococcus.—Dr. Byron presented a culture-tube containing pure cultures of the gonococcus. Five years ago he had successfully cultivated the gonococcus in this way on a medium composed of bouillon-agar containing two per cent. of cane sugar. One year after this Bumm cultivated this germ on blood-serum, and notwithstanding the assertion that it can only be cultivated on this serum, he had obtained much better results from the culture medium already described.

Primary Epithelioma of the Breast.—Dr. E. Hodenpyl presented a specimen of primary epithelioma of the breast, a condition so extremely rare that he had been unable to find a similar case on record. The patient was a widow, fifty-five years of age, who had been perfectly well up to four months ago, when, after a traumatism, a lump appeared in the breast. At this time it was about one inch in diameter, painless, and of slow growth; but about six weeks before her admission to the hospital it began to grow very rapidly, the skin became somewhat reddened, and there was a serous, and sometimes a bloody, discharge from the nipple. On admission the tumor measured six inches in diameter and seven inches in depth; it was quite painful, the skin was reddened over it, and there was a slight serous discharge from the retracted nipple. The breast was removed by Dr. McBurney, who found at the operation that this tumor was really a cyst containing over one pint of fluid. The growth presented a cauliflower appearance, and on microscopical examination showed the typical structure of a squamous epithelioma, such as is found in the skin, and the same arrangement of the cells which is found in stratified epithelioma elsewhere. When stained, the specimen showed the "spine cells" very well. There was no evidence that the tumor sprang from the skin, and the only possible explanation seemed to be Cohnheim's theory of aberrant cells. Gross, in his text book on "Tumors of the Breast," speaks of epithelioma, but his description would seem to apply to adenoma rather than to true epithelioma.

Acute Sepsis Following Catheterization. — Dr. George P. Biggs said that the specimen presented was from a man, seventy-one years of age, whose previous personal history was absolutely negative. Last June he began to have some difficulty in micturition, and the urine was occasionally tinged with blood. About three weeks before admission to the hospital, after a hard day's work, he had retention of urine. A physician relieved him temporarily by catheterization, but after this there was distention of the bladder and painful micturition. Three days before coming to the hospital these symptoms were increased, and he was again catheterized. The following day he had headache and vomiting; the urine contained considerable blood, and the patient appeared stupid. On admission the prostate was found enlarged. A catheter was passed without much difficulty, and bloody and purulent urine drawn off. After evacuating the bladder there was still an area of dulness about six inches in breadth, extending up nearly to the umbilicus, and this led to the diagnosis of a probable tumor. There was moderate fever, the stupor increased, and he died in three days.

At the autopsy the fundus of the bladder was found to reach nearly to the umbilicus, and the entire anterior wall was firmly adherent to the parietal peritoneum; the omentum was adherent to the fundus of the bladder, and the neighboring coils of intestine were covered with a little lymph; but there was no general peritonitis. The bladder contained a large quantity of offensive ammoniacal urine; the mucous membrane was necrotic over a large area; there were numerous hemorrhages, and marked trabecular hypertrophy. The prostate was hypertrophied and nodular. The bladder walls were infiltrated throughout, and on stripping away the anterior wall from the peritoneum several pockets of pus were found. The ureters were moderately dilated and much congested; the pelves of the kidneys were in a similar condition, and were filled with bloody and purulent urine. There was also a double pulmonary thrombosis which did not completely occlude the vessel. It probably formed just before death, as it gave rise to no symptoms. The pus was stained, but only large numbers of staphylococci were found. There was evidently a very acute infection following the catheterization.

Dr. Armstrong asked if there were any arthritic symptoms in the case.

Dr. Biggs replied that there was no history of any.

Dr. Armstrong said that about six years ago he had under his care at the Marine Hospital a sailor who was supposed to be suffering from acute articular rheumatism. He developed endocarditis and died. The autopsy showed not only arthritis and endocarditis, but nephritis and cystitis, and subsequent inquiry elicited the fact that he had had some trouble with the bladder, which had necessitated the introduction of an instrument. This had evidently caused infection. The lesions were very similar to those found in the case just reported.

Dr. Byron recalled a case of cystitis similar to the one presented. The lesions resembled those produced by the virulent form of the bacillus coli commune, which seems to have a special necrotic action.

Dr. Hodenpyl remarked that in an article by Schmidt, just published, is a report of fourteen cases of cystitis due to this micro-organism.

Careinoma of the Stomach; Ulceration of the Bowel.—Dr. George P. Biggs then presented specimens taken from a woman, forty-one years of age, who, when admitted to the New York Hospital on October 19th, presented the symptoms of chronic gastritis. She was of intemperate habits, and since an attack of la grippe last February had had a constant cough with mucous expectoration. Since April there had been morning nausea and vomiting, and moderate emaciation. The physical examination of the chest was negative; the abdomen was distended; the epigastrium was slightly tender; the urine was normal. While in the hospital she had a very profuse diarrhœa. No hydrochloric acid was found in the vomited matter. A diagnosis had been made of carcinoma of the stomach, but this was afterward thought

to be erroneous. An acute peritonitis developed shortly before death, which occurred on November 20th. At the autopsy no gas was found in the peritoneal cavity, and there was a small amount of lymph, and an unusually watery, almost milky, fluid. About four and a half inches from the pylorus the wall of the stomach began to thicken, and at the pylorus it was 1 ctm. thick. At this point the submucous coat was three-fourths of an inch thick, and rather soft. The mucous membrane showed papillary projections—the largest 1½ ctm. in diameter—projecting about three fourths of an inch above the surface. There were small nodular thickenings along nearly the entire greater curvature, and in some other places. The pylorus was narrowed to about 1½ ctm. in diameter, and the mucous membrane appeared to be superficially ulcerated. The duodenum presented nodular thickenings, and, apparently, superficial ulcerations. There was no new-growth in the pancreas, nor were there enlarged glands in the neighborhood of the stomach. The liver was rather large, and on section of the right lobe an ovoid mass about two inches in diameter was found deeply embedded in it. It was firm and distinctly outlined, and presented the appearance of carcinomatous deposit. There were no other deposits in the liver. An examination of frozen sections from the stomach and liver showed these to be the seat of carcinoma, but it was rather strange that the mucous membrane was so slightly involved.

Extensive and peculiar lesions were found in the ileum. In the lower two feet of the ileum the mucous membrane was destroyed, owing to the formation of numerous small round ulcers. The edges of these ulcers were undermined, and they appeared to have existed for some time. There were many similar ulcers in the large intestine, particularly in the descending colon. In the transverse colon were a number of pigmented points, which appeared to represent the healed ulcers of this type. None of these ulcers had perforated, but the peritonitis was probably the result of a direct extension of the inflammation from the deep ulcers. The spleen was of normal size; the mesenteric glands were slightly enlarged. Both lungs were the seat of extensive fibroid changes, apparently the result of the bronchitis originating in the attack of la grippe. Scrapings from the lungs and sections were examined microscopically, but no evidence of tuberculosis discovered.

The President said he had seen at an autopsy a similar thickening of the walls of the stomach. Sections were made of the thickened portions which did not appear to be carcinomatous, yet on examination they showed nevertheless the existence of carcinomatous deposits.

Dr. J. S. Ely referred to a recent specimen in which there was regular and uniform thickening of the walls of the stomach, involving all except an area about two inches in diameter. This infiltration was about ½ ctm. in thickness, was carcinomatous, and began at the pylorus.

Giant-cell Epithelioma of the Inferior Maxilla.—Dr. Biggs also presented a section of a tumor removed from a man, sixty-two years of age. Five years before he sustained a compound fracture of the inferior maxilla, and six months later, a small tumor developed in the floor of the mouth. This was removed at St. Luke's Hospital by Dr. Bull, nineteen months ago. It was said to have been a carcinoma. Subsequently a small nodule developed in the cicatrix and was removed by some other surgeon. Four months before admission to the New York Hospital a small tumor was observed in the submaxillary fossa on the side where the fracture occurred. When removed by Dr. Bull it was found to be a distinctly encapsulated ovoid body, measuring 3 × 2 ctm. in diameter. It contained numerous areas of degeneration, and showed on microscopical examination the structure of epithelioma. The "pearls" were very numerous and characteristic. Some lymphatic gland-tissue was also found. A peculiar feature was the enormous number of giant-cells, which resembled those found in giant-cell sarcoma.

The specimen was referred to the Microscopical Committee.

A Glio-sarcoma of the Brain.—Dr. Frederick Peterson presented a specimen of tumor of the brain, taken from a man fifty years of age. Up to five months ago he had had no symptoms except occasional dizziness. One morning last June he fell to the floor in a fainting attack. There was no paralysis and no symptoms of serious nervous disorder. He returned to business, but after two or three weeks began to feel weaker and to suffer from headaches. He gradually developed hemiparesis of the left side of the face, and of the left arm and leg, and the headaches and dizziness increased. When seen by the speaker, three weeks ago, he had in addition left hemianopsia and double optic neuritis. A diagnosis was made of tumor of the internal capsule. The question of operation was broached by the attending physician, but it was not thought advisable owing to the absence of symptoms of irritation of the cortex. The specimen showed that the tumor did not affect the left side or any of the cranial nerves.

Cerebral Thrombosis; A Kidney with two Pelves.—Dr. J. S. Ely presented specimens taken from a woman, sixty-four years of age, who for the past ten years had had dyspnœa on slight exertion, accompanied by cardiac palpitation. Six years ago the left breast was amputated for carcinoma. Five years ago she suddenly became unconscious for about four hours, but there was no aphasia or paralysis. One year ago she again became unconscious, this time only for a few minutes. On November 16th she suddenly fell to the floor, and when found, fifteen minutes later, the tongue deviated to the right, her voice was thick, there was partial paralysis of the left side of the face and of the left arm and leg. When admitted to Bellevue Hospital, the following evening, the pupils were equal and responsive, the pulse full, regular, and slow, the cheeks flapping with expiration, and there was partial paralysis of the left side, but no loss of sensation. She was semi conscious. On November 19th the pupils were contracted and unequal, and she was unconscious. She died early the next morning. The autopsy showed nothing abnormal about the dura mater or pia, but the right side of the brain was softer than the left, and the cerebro-spinal fluid was increased in quantity. There was extensive atheroma of the arteries at the base of the brain. In the right middle cerebral artery was a plug which completely occluded it. The softening was limited to the area supplied by this artery. There was no evidence of hemorrhage. The lungs were œdematous; the heart was enlarged and the aorta atheromatous.

The left kidney had two pelves, each one having its own ureter. The two ureters united about one inch from the bladder. The other kidney showed no such malformation. Both kidneys were the seat of advanced chronic diffuse nephritis.

Pseudo-hermaphrodism.—Dr. Ely also exhibited a male child whose external genitals resembled those of a female. This appearance was due to a complete hypospadias, and a fusion of the scrotum, and to the fact that the testicles had not descended. This is the commonest form of so-called hermaphrodism.

The Society then went into executive session.

A New Test for Albumin.—M. Spiegler has devised a test for albumin which is said to be endowed with extreme delicacy, its sensibility being 1 in 350,000. It is prepared as follows: Perchloride of mercury, 2 parts; tartaric acid, 1 part; distilled water, 50 parts; glycerine, 5 parts. The urine to be examined is first rendered strongly acid with acetic acid and filtered. With a pipette some of the filtered urine is dropped on to the surface of 2 c.c. of the testing fluid. The presence of albumin is revealed by the development of a white ring at the point of contact of the two liquids. The presence of peptones does not interfere with the success of the analysis.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

BENIGN OR MALIGNANT TUMOR—PATHOLOGICAL SOCIETY—FIBROMYOMA BECOMING SARCOMATOUS—CANCER AND ORGANISMS — TAR CANCER — RUPTURED SACCULUS OF BLADDER FOLLOWING STRICTURE—DISEASE OF KNEE-JOINT — CHOLESTERIN IN RENAL CYST — THE YEAR'S INCREASE OF MEDICAL MEN—DEATHS OF PROFESSOR M. MARSHALL, MR. ARTHUR GAMGEE, AND DOWAGER LADY GULL.

LONDON, January 5, 1894.

DOES a benign tumor undergo a histological transformation and put on malignancy? On Tuesday last (2d inst.), a case was related at the meeting of the Pathological Society by Dr. Lee Dickenson, which he considered one instance of fibromyoma of the uterus becoming sarcomatous. The patient was forty eight years of age. A uterine tumor had been noticed about a year; then it began to grow very rapidly, with exhausting discharge and indications of compression of the pelvic viscera. She was so exhausted that operation was not advised. At the autopsy the tumor was reported to be about the size of a melon—rather an indefinite statement that—and it presented the characters of a fibromyoma. A portion had sprouted into the pelvic cavity, and this had the structure of a spindle-celled sarcoma. Some of the growth had calcified. There were no metastatic growths. The author thought that the sarcomatous tissue originated in muscle-fibre cells. M. A. Doran thought that a myoma might become malignant as such, the metastatic growths having a myomatous structure. He observed that many rapidly growing fibroids were not malignant, and small ones, which at first seemed to have taken on malignancy, might turn out eventually to be benign. Further, he said fibroids might become œdematous or they might become the seats of carcinoma. The occurrence of gland-tissue in many of the uterine tumors of this kind may account for this fact.

Mr. Jackson Clarke then drew attention to a paper by A. Korotneff, in the *Centralblatt f. Bakteriologie* of March 23d, not long after his own communications to the Society on the relation of sporozoa to cancer, and of which I gave you an account at the time. The Russian biologist has since published his views in book-form, and Mr. Clarke considers they confirm his own prior investigations. Mr. D'Arcy Power demonstrated the histology of a squamous-celled carcinoma removed from the scrotum of a man who worked in clothes which were often saturated with gas tar in the peripheral cells of which were appearances which he admitted were faintly suggestive of cancer bodies. Hereupon Mr. Shattock proposed that the preparations of Mr. Clarke and Mr. Power should be referred to the Morbid Growths Committee to criticise and report upon, but not with a view of any dogmatic statement as to their meaning, for he thought just now it was of great importance to be clear as to the facts. Dr. Kanthack said he had often seen epithelial-cell fusions in carcinoma. The body described by Mr. Clarke as a spore-bearing cyst he regarded as a capillary containing leucocytes. The "cancer bodies" are evidently destined to afford food for further discussion and investigation.

Mr. F. C. Wallis then related a case of stricture after amputation of the penis in which a sacculus of the bladder formed and ruptured. After death the extravasation was found to be extra-peritoneal and the rupture had taken place in the upper part of the bladder and to the left of the urachus.

Mr. Davies Colley showed a dried specimen—the bones of a knee-joint which he had excised thirteen years ago, for what was then considered osteo-arthritis. The man had syphilis twenty years before, and Mr. Colley thought the appearances corresponded with what are now considered syphilitic, and perhaps the case might be thought to be one of Virchow's syphilitic chondro arthritis. Mr. Spencer remarked that there was no evidence of syphilis going on at the time of the operation, nor were any traces found in other organs at the autopsy. It was rare to find joint disease in association with tertiaries of the bones. He thought the clinical aspects resembled septic arthritis, and the scooped out cavities were suggestive of tuberculous disease.

Mr. Bowlby did not consider syphilitic joint disease rare, though he admitted that extensive destruction was uncommon. The painlessness of the affection often caused it to be overlooked. This case he regarded as syphilitic. Neither eburnation nor the deep, dug-out pits occurred in septic arthritis. The aricular osteophytes did not resemble those of osteo arthritis, but rather such as occurred in inflammation. Moreover, there was an absence of the lipping of osteo arthritis.

Mr. H. Fenwick showed a specimen of sacculated kidney with partial obstruction of the ureter by an impacted concretion. Nephrotomy had been performed when clear urine was evacuated glistening with crystals of cholesterin. Death occurred ten days later, and at the autopsy it was found that the calyx was enormously dilated from the presence of stone in the ureter, and in the calyx there was cholesterin.

There are only two cases of cholesterin renal cysts recorded in the Transactions. It has sometimes been denied that cholesterin crystals may be passed in the urine. Dr. Murchison's case, however, is proof that this may occur, and I have met with one in consultation, the details of which I cannot record, but it quickened my interest in Mr. Fenwick's exhibit.

We are often lamenting the overcrowding of the profession, and with the New Year comes a sharp reminder that the pressure increases.

Here is the new medical directory, and one of the earliest bits of information it contains is that 1,013 is the increase in the number of names over the number last year. Actually 1,013 additional competitors, although 639 have been considerate enough to leave this struggling world. In London, alone, there are now 5,590 qualified practitioners, which is equal to about 1 to 750 of the total population, and then there is the ever-increasing army of quacks and pretenders to medical wisdom of various kinds—to say nothing of the abuse of the out patient departments of the hospitals and increase of cheap dispensaries.

Truly, the lookout of the profession is not a very lively one, and the maintenance of its dignity is becoming impossible.

Professor Milnes Marshall has met his death from a mountaineering accident at the early age of forty-one years. Professor Gamgee has lost his only son, a brilliant youth of seventeen, who committed suicide in a state of temporary insanity while at college. The Dowager Lady Gull, widow of Sir W. Gull, died on the 2d inst., aged seventy-four.

DO THE SICK EVER SNEEZE?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of December 23, 1893, you ask the question "Do the Sick ever Sneeze?" At the risk of being held responsible for "the consequences of an awful certainty" I am constrained to give truthful answer to your query, believing that so important a matter ought not to go longer unsettled. That the sick do sneeze I have proved by painful, personal experience. It was during an attack of acute pleuritis that I did my memorable sneezing — memorable because distressing. On several occasions, when from dread of the pleuritic pain I had for a length of time repressed an inclination to cough, I was suddenly seized by a violent fit of sneezing. And *such* sneezing! Ye gods and little fishes! How I wished that I had coughed instead, for I was able to control in a measure the violence of the cough, but the sneeze had its own sweet will with me, quite regardless of nose-pinching and various other common devices for checking sternutation. How it did stir up that ten-

der spot and put adhesions violently on the stretch? Yes—and I speak feelingly—the sick do sneeze.

Another case in point is the following: Not long since, a patient of mine, suffering from some acute illness the nature of which I do not now recall, suddenly, during my visit, sat up in bed and sneezed so long and violently that I was alarmed for her. When she had recovered her voice she assured me that she *enjoyed* that sort of thing—adding that "all our family sneeze so." It was a family trait and they were all proud of it. I thought nothing further of the matter at the time; now, however, I know that I was favored above most mortals, and witnessed a strange and unusual sight. For my own case, I had never been a "sneezer," and kicked—figuratively, at least—at being compelled to take up the habit at so inopportune a time. Now my regrets have fled, for I believe that I "snoze" when it hurt, so that I might remember and thus be able to help clear up this great mystery. The sick (some of them at any rate) do sneeze.

Very truly yours,

E. McALLISTER, M.D.

REDLANDS, CAL., January 9, 1894.

HUMANE TREATMENT OF MORPHINISM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Having read in your issue for December 23, 1893, a paper by Dr. J. B. Mattison, entitled "The Modern and Humane Treatment of the Morphine Disease," I desire to add a word in support of the superior excellence of the method there laid down.

I do not hesitate to assert that it represents the most decided advance in the therapeutics of morphinism yet made. Between all other methods hitherto presented there has been little to choose, all equally entailing a degree of suffering which exceeds the limit of voluntary endurance, the plan of abrupt suspension being the most barbarous of all. In my own mind it may be a serious question whether the shock to the nervous system resulting from this atrocious method may not even hinder subsequent convalescence.

In this connection permit me to refer to an anonymous paper published by the writer in *The New York Medical Journal* for January 7, 1893, entitled "The Cure of the Morphine Habit by Sulphate of Codeine." The conditions obtaining at the time of this publication have since changed so that I am at liberty to refer to it as a matter of convenience. The paper details a case in which the morphine habit after a continuance of nearly two years was voluntarily abandoned by a plan practically the same as the Mattison method.

The great central feature of this latter-day therapeutics of morphinism lies in the gradual disinthralment of the victim through the substitution of the milder allied alkaloid of opium. I am fully convinced that time and experience will establish the Mattison method as the standard treatment of morphinism—a boon to humanity and a credit to American medicine.

F. O. MARSH, M.D.

CINCINNATI, O.

ONE WAY TO OVERCOME CRIMINALITY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The article in the MEDICAL RECORD of January 13th on "Criminal Anthropology" closes with an eloquent paragraph upon the injustice of the criminal's treatment by society. The argument is the old one of his irresponsibility. Impulse to crime is an inherited taint. The criminal is an atavistic creature no more to be blamed for his acts than is the child of syphilitic parentage to be called to account for his unlovely skin, or bones, or teeth.

Now all this must be freely admitted. Yet no one seems willing to face the plain inference. It is surprising how much sociology knows, and how little it dares do. Articles on penology usually close, as does the one which prompts these lines, by "What will you do with the Criminal?"

The reply seems fairly to jump at one from the argument. Manifestly, prevent his doing for others what his depraved parents did for him. Why go on eternally imprisoning and executing this aberrant race? Why not once for all prevent their reproducing themselves? If society may do the one, it may do the other. If you may kill a murderer by process of law, you may do him a less violence. And yet habitual criminals, known as such, recognized at a glance by the experienced, bearing all the characteristic marks which Dr. Weir so interestingly illustrates, are discharged constantly from our penal institutions, to go forth and bring into existence other vitiated moral types equally irresponsible, who will in turn do evil all their days, and leave children to propagate the heritage. Irrationally, it seems to me, society permits this to continue, and prefers to punish from generation to generation unjustly, rather than prevent.

Now, supposing that every habitual criminal, every man or woman convicted twice of deadly assault, or highway robbery, every man convicted twice (many would say once) of rape or other abominable crime, should be legally and aseptically castrated? Who can doubt that such legislation would be twice blest in its results? In the first place, the criminal breed would come in a few generations to an end, and the criminal type be stamped out root and branch; and, in the second place, the deterrent effect of such a statute would be (I believe I speak within bounds) greater than that of the death penalty itself.

This is not a savage doctrine. It is merciful. It is merciful to unborn generations of wild beasts in human form, whom society must, for its own protection, treat cruelly and unjustly, as judged from the ideal standpoint; and it is merciful to that innocent army of martyrs, who, as they were in the beginning, are now, and apparently ever shall be, their victims.

With great respect,

Yours, etc.,

WILLIAM S. CHEESMAN, M.D.

AUBURN, N. Y., January 14, 1894.

THE HAPPY THERAPIST.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Under the title "Locomotor Ataxia Treated by Phosphatic Injections," there has recently appeared in *The Lancet*, from the pen of Dr. Forbes Winslow, a brief clinical memorandum setting forth the curative properties of phosphate of soda administered hypodermatically. There is something decidedly refreshing in being told that a disease universally regarded as incurable, yields in the hands of one individual such earnestly looked-for results. Were it not for the dignity of the journal, however, in which this last contribution to happy therapy appears, it would scarcely deserve a passing notice even to condemn it. In the first place, there are absolutely no etiological factors or pertinent symptoms of moment given to establish the diagnosis which the writer states with so much positiveness. He is apparently satisfied that his readers will be content with his diagnosis, fortified and corroborated, as he tells us in a later issue of the journal, by the written statement of two eminent physicians, neither of whom, it may be mentioned by the way, ever laid claim to special diagnostic skill in diseases of the nervous system. The fragment of history that accompanies the report is as follows: A young man suffering from marked symptoms of locomotor ataxia which had developed during the previous two years, and apparently caused by a fall from a horse. For significant symptoms it is stated that there was complete loss of co-ordination in his movements. He was quite unable to walk without the assistance of two sticks, and when seated in a chair he could not raise himself without assistance. The clinical history is tersely summed up as follows: "The case was a very characteristic one"—a summary which we would gladly consider, if the symptoms and pathognomonic signs of

the disease had been given. As it is, however, we cannot escape the conviction that the case was suspiciously like one of traumatic neurosis of a pseudo tabic type.

The report of this case prompts us to say a word regarding the utility of such communications. It matters not how famous the writer may be, if he wishes to introduce therapeutic innovations and claim for them curative results, he owes it to the intelligence of the profession of which he is a member, to communicate his investigation in all its details. And especially are his readers deserving of all the details of cases which lead to the forming of an absolute diagnosis.

In the case in question, not a single symptom or sign that points with any accuracy to the diagnosis has been vouchsafed. The written certificates of two consultants, even if they were sworn to, would not carry the conviction that such consultants were infallible in the diagnosis of locomotor ataxia. As regards the advisability of reporting one case of locomotor ataxia apparently going on to recovery, we will content ourself with saying that if such became the custom, there is scarcely a neurologist of ten years' standing in the country who could not easily duplicate such a report from his practice.

Dr. Winslow concludes his article with the following remark, which for unsuspecting credulity and *naïveté* is positively refreshing. "Since I first became cognizant of the treatment I have tried it in other cases, and in all the disease appears to be yielding to its use." Neurologists appreciate with what anxiety the unfortunate ataxic who has searched from one Mecca to another, hails the advent of a new remedy which is held out to him with promise, and what sacrifices he will make to avail himself of that treatment. It is, therefore, unfortunate that at the present day any physician cognizant of the present status of the pathology of disease, should lend himself to the propagation or continuance of a treatment that has absolutely no *raison d'être*, theoretically, practically, or experimentally. Something more than a year ago, Crocq, of Brussels, made a communication to the Paris Academy of Medicine, on the therapeutic properties of phosphate of soda used subcutaneously in a 1 to 50 solution of cherry-laurel water. He pointed out particularly, that upon nervous patients it produced the effect of a powerful tonic, and that in functional cerebro-spinal trouble it was a useful remedy. He also spoke of its use in locomotor ataxia, but did not urge it as a panacea in this latter disorder. It is on this communication, probably, that Mr. Winslow instituted treatment in his case. He does not, however, take us into his confidence in this matter, but says, in a very mysterious way, that "phosphate de soude," in combination, was injected into the neighborhood of the spinal cord. No mention is made of the quantity used, the dose, frequency, etc Therefore, we very naturally are confronted with the question, what does it profit the medical profession to know that a certain physician has cured a case of locomotor ataxia with a drug used in combination, when the combination is not given? Frankness compels us to say that this manner of reporting cases reminds us forcibly of a popular treatment for an another neurosis instituted by a physician in a small town in Illinois. He, however, is open in the matter and says, not implies, that it is the combination more than the gold which is efficacious.

We may be permitted to say that about a year ago, after Crocq's article came under our observation, that with a view of putting his claims to the test of experience, six cases, three of genuine tabes and three of different forms of neurasthenia, were subjected to treatment according to his directions for upward of three months, without the slightest manifestations of bettering on the part of the tabic patients, and none of permanency worthy of comment in the others. At divers times after this it was tried on individual cases, with the same results. The matter was not considered of sufficient importance to relate, and with the exception of an editorial comment in the MEDICAL RECORD, wherein these facts were referred to, the matter aroused no notice on this side of the water. We hoped that it had dropped into deserved disesteem with promptness equal to that of its birth, and we record with regret this latest evidence of its attempted resuscitation.

JOSEPH COLLINS, M.D.

LIFE TENURE ON HOSPITAL BOARDS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In regard to the conduct of the Managing Board of the New York Infant Asylum, concerning which so many vituperative articles have lately appeared in your columns, it seems to us to be a step in the right direction and worthy of imitation by hospital management in general. We fail to see wherein the Board has cause for complaint in this case. Of course it is natural, for men who have obtained positions on hospital staffs, to desire to retain life memberships. These favored few of all the great medical body have a monopoly, so to speak, of the material provided by the wealth of the charitable rich, and the misfortunes of the suffering poor, for becoming and remaining leaders in medical thought and action, while many of the brightest intellects in the profession, like mute, inglorious Miltons, must content themselves with witnessing the operating theatre performance, and listening in many instances to the self-glorification of men who hold high positions on hospital staffs through no special adaptation on their part.

We have the highest respect and admiration for our great surgeons and great physicians, and would not detract one iota from their well-earned distinction, "but render to Cæsar that which is due to Cæsar;" but we do believe that the American system of hospital régime is more conducive to the development of professional autocracy than to that of the best scientific skill and medical genius.

This may be a sordid manner of looking at this matter, but the lever of self-interest will be found in the fulcrum of all benevolence, though the length of the power-arm may vary greatly. Yours respectfully,

JOSEPH S. LOCKHART, M.D.

4 TEMPLE STREET, BOSTON, MASS.,
December 28, 1893.

THE NEW YORK INFANT ASYLUM AFFAIR.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of the MEDICAL RECORD for June 24, 1893, the editorial entitled, "A Medical Board Resigns," contains the following sentence: "We shall watch with interest for the list of gentlemen who accept the positions thus vacated." In the MEDICAL RECORD of November 25, 1893, the editorial entitled, "Medical Boards and Hospital Managers," closes with this sentence: "Nevertheless, we venture to predict that there will be some very radical changes in the conduct of the New York Infant Asylum: and that it will be a long time before physicians of repute will connect themselves with an institution whose management has so thoroughly discredited itself." That a serious injustice was done to a most worthy charitable institution in the two articles alluded to, will be apparent to anyone who will read in your issue of December 2, 1893, that portion of the Report of the New York Academy of Medicine, on pages 726 and 727, referring to the "New York Infant Asylum Affair." As further evidence of the error into which you have been led I beg to hand you a list of the officers of the Asylum, and of the members of the new medical board elected at the annual meeting of the Board of Managers, which took place on the 16th inst. These were as follows:

President of the Board of Managers, J. Edward Simmons: *Vice-President*, Fred. de Peyster; *Treasurer*, L. B. Griffin; *Secretary*, Gherardi Davis. The Medical Board: *Consulting Physicians*, L. Emmett Holt and W. P. Northrup: *Consulting Obstetricians*, William T. Lusk, Edward L. Partridge; *Attending Physician* at Sixty-first Street, J. Lewis Smith; *Attending Obstetricians*, J. M.

Mabbott, H. McM. Painter, E. E. Tull; *Attending Physicians* at Mount Vernon, A. M. Campbell, W. F. Greene; *Consulting Sanitarian*, C. F. Chandler; *Attending Sanitarian*, C. Pellew.

The above information I furnish you with much pleasure, and leave it to your sense of propriety to publish as much or as little of it as you desire.

Yours very truly,
H. D. Nicoll, M.D.

January 17, 1894.

[We notice also that the conditionally radical change in the management has been made, and the result has very naturally followed. If it were otherwise no medical man who respected himself would accept an appointment.—Ed.]

THE SYSTEM OF MEDICAL SERVICE IN HOSPITALS.

To the Editor of the Medical Record.

Sir: Permit me to refer to Dr. J. West Roosevelt's candid letter, and the editorial comment appended thereto, in the last number of your valued periodical. Dr. Roosevelt's question: "Do you, Mr. Editor, or does anyone, think that the quality of medical talent at the service of the hospitals of this city would be improved, or that the patients in these institutions would receive better care, if a money compensation were offered?" touches the vital point of the inquiry. Though extremely interesting and of immense practical importance to the practitioner, the influence exerted by our city hospitals upon the temporal rewards derived from practice by medical men, cannot fairly be expected to sway the actions of managing boards, whose position in this respect was very fairly characterized by Dr. Roosevelt's communication. But it is the duty of hospital managers to take in consideration the question quoted above, and directed to you by Dr. Roosevelt.

It is not probable—taking matters very broadly—that the quality of medical talent at the service of the hospitals of this city would be improved, as it is a well-admitted fact that boards of managers, as a rule, are anxious to, and generally successful, in securing the best talent. But there is not the least doubt in my mind that "the patients in these institutions would receive better care if a money compensation were offered."

The reasons for this opinion are many and obvious, well known to everyone familiar with the management of hospitals both abroad and at home. Of these reasons one or two only may be hinted at in this letter. Where the visiting men of a hospital are paid for their services, it is customary to compel them to devote the principal part of their time and labor to their hospital service. Hence they must "make rounds," that is, visit every patient in their charge personally at least once per day, their hospital visit being usually held in the morning, when all operative work is also attended to. With a service of one hundred and fifty to one hundred and eighty beds, this morning visit involves on an average two and one-half to three hours work. Every patient's case is daily observed, and the treatment is continuously and directly influenced by the chief of the service. He is paid for his work, which is expected of him, and the patients derive immense benefit therefrom.

After his hospital duties are fulfilled, the medical man may devote the remnant of his time to study or to practice. Here, then, the hospital comes first, private practice is a secondary matter. Now let us compare this with the ways of our hospitals. Everyone of us must earn his bread first by practice, and whatever time is left over is given to the hospital; in some cases more, in others less, in almost all cases much less than would be desirable. Morning and evening rounds are held by inexperienced young men, the visits of the attending medical men are often irregular as to their time, hurried, and incomplete; and who can blame the busy practitioner for this? I do not mean to say by these remarks that gross neglect of patients is frequent in our hospitals. From personal experience, I can testify to frequent examples of unselfish devotion to their hospital work by men of my narrow acquaintance, some of whom have neglected and are neglecting their private remunerative practice for the sake of fulfilling conscientiously their obligation toward their hospital patients. That gross neglect, however, does not occur more frequently is explained by the short terms of service prevailing in most of our institutions, a makeshift of the meanest kind, the ill consequences of which are most damaging to the poor patient. Just imagine what sort of a bank or regiment it would be, where the president or colonel were changed regularly every three or four months! and this is just what happens in all our hospitals as a matter of routine; that is, the routine is the killing of every possibility of a well-organized hospital routine. If a poor, struggling institution must, as a matter of necessity, accept the crumbs falling from the table of our leading medical men, well and good, the patients should be content with what they can get under the circumstances; but why our wealthy, richly endowed corporations, or rather their managers, still should continue to humbug the public by pretending to give their patients the best and most efficient medical service, when they are only doling out as it were the pickings and leavings—precious as these be in themselves—of the work of some talented medical men of public spirit; why in fact they should usurp the name of first class medical institutions with a third and fourth class system of medical service done by first class men, when there are abundant means at their disposal to *pay for a real first class system of medical service;* why all this should continue so forever in enlightened, progressive, and liberal America, cannot be comprehended.

It stands to reason that this system would involve a permanent service of one paid man to each hospital department, which would at once result in genuine scientific progress and practical improvement of methods, due to the stimulus to personal ambition engendered by undivided responsibility.

I shall conclude by assuring you, Mr. Editor, that the relations of medical men thus situated to their boards of managers would become quite different from what they are at present; duties would be more exacting, more strictly circumscribed, and rights and authority in proportion augmented and solidified. Though the theme is interesting, important, and far from exhausted, out of consideration for your limited space it is time now to stop.

Arpad G. Gerster, M.D.

New York, January 17, 1894.

IS THE WYETH METHOD OF HIP AMPUTATION PROPERLY NAMED?

To the Editor of the Medical Record.

Sir: In the issue of the Medical Record of December 16, 1893, I set up the claim that Wyeth's method of amputation at the hip-joint is simply a modification of the method known to German surgeons as Volkmann's. In the issue of the same journal of January 13, 1894, Dr. Wyeth denies this statement, and also denies that Volkmann originated any method of hip amputation. In support of the latter claim he cites numerous German works, among them König and Heinicke, in which he is unable to find any description or mention of any such operation. This is indeed strange. König devotes exactly one hundred and fifty lines of space to the subject of disarticulation at the hip-joint. Of these one hundred and fifty lines, twenty-four are devoted to the description of the operation he attributes to Volkmann. On page 344, of Vol. III., published in 1889, he says: "Decidedly the best method, particularly with imperfect assistance, is the preliminary amputation of the thigh and subsequent extirpation of the bone, as has lately been advised by Volkmann; as it is possible to employ Esmarch's anæmia until the vessels have been secured.

After wrapping the leg up to the flank, the rubber tube is so applied that it runs in the direction of Poupart's ligament from the commisura femoro-scrotalis outwardly to the incisura semilunaris of the ileum, between the upper and lower iliac fossæ. The tube must be held here by the hands of an assistant, or by three pieces of bandage thrown around it and drawn upward, that the divided and retracting muscles may not permit the tube to slip off. As Veitch has advised, one then makes skin flaps for a covering according to the material, then divides the muscles three finger breadths below the flank, lays the bone bare to its middle, and saws it through at that point. Now careful control of the hemorrhage, first while the tube is still in position, then after its removal. After the bleeding has ceased the bone is extirpated—best subperiosteally. The capsule is not removed, the zona being incised by a probe pointed knife and the fibro-cartilaginous reinforcement of the limbus (cotyloid ligament) nicked. Then the head may be drawn forward, and finally the ligamentum teres divided. The operation is also successful by the circular method without the side slit, while by the flap method the great trochanter is usually more or less exposed. Still there is no objection to laying the trochanter free by a side incision over it reaching to the border of the flap, especially as the skin covering it is left very thin after its removal, and should be incised to permit the passage of a drainage-tube to the acetabulum."

On page 868 of his "Compendium der Chirurgischen Operations- und Verbandlehre," published in 1886, Heinicke says: "The constriction of the upper part of the thigh with a strong rubber tube is only applicable if one departs from the usual methods of exarticulation. After constricting, a circular incision should be made below the tube and at a suitable distance from the joint, through all the soft parts to the bone. The skin must be retained to a somewhat greater extent than the deeper structures. When the bone has been exposed it should be sawed through and all visible vessels tied. Then the tube should be removed, any bleeding vessels secured, and finally the bone and joint made accessible for disarticulation by the addition of an incision upon the outer side reaching to the point of the great trochanter. The circular will thereby be transformed into an oval incision. The disarticulation itself has to be accomplished by the division of all soft parts close to the bone."

It will be observed that Heinicke describes an operation remarkably like Wyeth's, but fails to give the name of its originator.

I am sorry the other works Dr. Wyeth mentions are not at my command. I might again be more successful than he in finding in them a description of this operation, as I also find it in works Dr. Wyeth has not mentioned.

On page 553 of Leser's "Specielle Chirurgie," 1890, I find the following: "Or you may choose the method advised by Volkmann. You make a high thigh amputation in the usual manner with anterior and posterior flaps, and afterward exarticulate the stump at the joint. It is here possible to employ the advantages of Esmarch's anæmia. After the leg has been rendered blood-empty in the usual manner, you lay a tube around the thigh close to Poupart's ligament and have it held by an assistant to prevent possible slipping. Then one makes the flaps or circular incision for a thigh amputation, ligates the vessels and saws off the bone; now one dissects the stump out of the soft parts, protecting the vessels, and disarticulates the head out of the joint."

On page 529 of Vol. II. of his "Manual of Operative Surgery," Treves gives directions for the application of the elastic constrictor, and on page 535, quoting from Barker's "Manual of Surgical Operations," 1887, describes Esmarch's operation, which he says "is identical with that described by Veitch, Lacauchie, Volkmann, and others." His description is so similar to those given above that its repetition is unnecessary.

The first I knew of this method was learned from Volkmann's own lips in 1886, while serving upon his staff. During the two and a half years of my connection with his clinic I heard the operation described repeatedly, and claimed for him both by himself and by Professors Oberst and Krause. Unfortunately we had no case in that time where the operation was indicated. In 1887, I heard Dr. Eugene Hahn, director of the Berlin City Hospital at Friedrichshain, describe the operation and attribute its origin to Volkmann.

From the above it will be seen that, in the opinion of some authorities well known to the surgical world, Volkmann did originate a method of hip amputation, and one to which Wyeth's bears a striking resemblance.

Dr. Wyeth, in speaking of the modifications of his operation, says:[1]

"Dr. Deaver was equally successful in holding the tubing well up by two strips of roller bandage, one before and one behind, held by an assistant, and thus dispensing with the needles." Does the operation thus performed differ from the one above described and attributed by competent authorities to Volkmann? No. It then becomes the good, old, original Volkmann operation.

I am perfectly willing to give to Dr. Wyeth the credit of introducing the pins and thus needlessly mutilating the thigh, and of permitting the constrictor to lie until the disarticulation has been completed, although he says if any difficulty in disarticulation should be experienced the tube should be removed, and to Drs. Murdoch or Lanphear that of not dividing the bone. But wherein does this modify the principle of the operation? In no particular. The method is and must remain one known before Wyeth either conceived or executed his. Concerning the operation done by Dr. Walter Brashear in 1806, I know nothing. He probably performed the operation as stated, but his method became so completely lost that, when resurrected more than fifty years afterward, the name of almost anyone but Brashear was attached to it.

Is Wyeth's method properly named? Should it not be called Volkmann's, or if we desire to go still farther back, Brashear's. It certainly is not Wyeth's method. Dr. Wyeth himself admits it to be a modification of Brashear's.

Nuclein the Germicidal Principle of Blood-serum.—Professor Victor C. Vaughan states (*Medical News*) that he has discovered the presence of nuclein in the serum of the blood, and isolated it; also, that this nuclein has germicidal properties. He believes that the fact that the germicidal constituent of blood-serum can be isolated has an important practical bearing. Blood-serum therapy has proved impracticable on account of the large amount of the fluid which must be injected. "Nuclein-therapy now promises to enable us to avoid this difficulty, and possibly the near future may find us using this agent in the treatment of disease. The nuclein may be obtained from an animal rendered immune to diphtheria, and a sufficient quantity of this injected into the blood or under the skin of a child suffering with this disease may effect a cure, but we will not prophecy. The future will tell us what it has in store when the future shall have become the present.

Disinfecting the Intestinal Tract.—Quite recently, Dr. Ernst Freund has succeeded in completely sterilizing the contents of the intestine by the administration of peppermint-oil, which is preferably exhibited in the form of the following capsules: menthol, gr. 1½; oil of sweet almonds, ♏ 4–8; from 6 to 8 capsules in the twenty-four hours. The dose of menthol administered never exceeded fifteen minims in the cases in which this method of treatment was tried by Dr. Singer, and the author has never observed any unpleasant symptoms to follow the use of this remedy. The administration of purgatives with the same end in view did not prove so satisfactory.

The Association of American Medical Colleges. *Notice of Proposed Amendment to Sec. V., Art. 3, of the Constitution.*—At a meeting of the faculty of Rush Medical College, held December 7, 1893, the faculty by unanimous vote passed the following resolution, to wit: *Resolved*, That Sec. V., Art. 3, of the Constitution of the Association of American Medical Colleges be amended to read as follows: "From students who intend to graduate in 1899, or in subsequent classes, four years of medical study and an attendance upon four annual courses of lectures of not less than six months' duration each will be required. Provided, that graduates of literary colleges who have taken a course of four years, including study in the natural sciences, and graduates from universities and colleges that furnish a suitable course of scientific studies, graduates of schools of pharmacy that require three years of study and adequate preliminary education, and graduates of dental colleges requiring two years of study and adequate preliminary education, may be admitted to the second year's work or course of lectures in the college without examination." The present wording of Section V., Article III., is as follows: "Candidates for the degree of Doctor of Medicine shall have attended three courses of graded instruction of not less than six months each, in three separate years." It will be observed that the adoption of the proposed amendment will require of all matriculates of the session of 1895, attendance upon four full courses of instruction before receiving the Degree of M.D. Recognizing that the proposed amendment, if adopted, would necessitate the formulation of a general curriculum of study for the various branches of the courses, and perchance, other necessary changes or additions to the by-laws, the President, Dr. N. S. Davis, has appointed the following named persons to act as a special committee to prepare a new schedule of minimum of requirements, and to submit the same at the fifth annual meeting, to be held in San Francisco, at 3 P.M., Wednesday, June 6, 1894:

Committee. — E. L. Holmes, *Chairman*, President Rush Medical College, Chicago, Ill.; Rignald H. Fitz, Harvard Medical College, Boston, Mass.; Victor C. Vaughn, Dean Department of Medicine, University of Michigan, Ann Arbor, Mich.; William Osler, Johns Hopkins Medical College, Baltimore, Md.; William E. Quine, President College of Physicians and Surgeons, and President Illinois State Board of Health, Chicago, Ill.; P. S. Connor, Ohio Medical College, Cincinnati, O.; Dudley S. Reynolds, Hospital College of Medicine, Louisville, Ky.; Perry H. Millard, Dean College of Medicine and Surgery, University of Minnesota, Secretary Association of American Medical Colleges, St. Paul, Minn.

The committee will hold a meeting in Chicago, at the Grand Pacific Hotel, at 3 P.M., Wednesday, February 7, 1894. Colleges, members of the Association, are requested to aid the committee in their work by advice or representation. It is particularly desirable that colleges, members of the Association, be represented by a formally appointed delegate at the forthcoming session. The proposed amendment, if adopted, marks a most important era in the history of medical education in this country. Colleges unable to be represented by a regularly appointed delegate, will confer a favor by informing the Secretary of their attitude on this amendment, that the same may be submitted or made known to the convention before the final action is determined. Colleges electing delegates are requested to indicate in their credentials if they have full power to act, and to furnish the Secretary the names of the delegates elected as soon as practicable. Colleges are entitled to one delegate each. A proxy cannot be delegated to a person not directly connected with the college desiring representation. In the consideration of this question it is proper that I refer you to the recent action of the American Medical Association and of the Iowa State Board of Health, regarding the enforcement of the four years' course by the colleges wishing their Alumni to receive recognition subsequent to 1895. There are at present seventy-one colleges members of this Association. Article VI. of the Constitution reads as follows: "This Constitution shall not be altered or amended except by a written notice to all the members at least thirty days previous to a stated meeting, and by a vote of two-thirds of all the delegates present at such meeting.—PERRY H. MILLARD, Secretary Association American Medical Colleges, St. Paul, Minn.

Sanitary and Medical Service on Board Emigrant Ships.—Report of the Committee of the American Public Health Association on "Sanitary and Medical Service on Board Emigrant Ships," presented by Medical Director Albert L. Gihon, United States Navy, Chairman, at the session of the twenty-first annual meeting of the Association, held at the Art Institute, Chicago, Ill., Wednesday, October 11, 1893.

Your Committee beg to report the following concise statement of their views as to the organization of such a sanitary and medical service, on board vessels engaged in bringing immigrant passengers to the United States, as the experience and intelligence of this age make a necessity among civilized and enlightened nations. They are of opinion, and advise:

First: As to the location and dimensions of the quarters for emigrant passengers, the number of berths in each, and the provisions for their ventilation and cleansing:

That the preferable location for such quarters is abaft the midship section of the vessel; that single males' quarters shall be distinct from those occupied by women and children, and that if any are forward the midship section, it shall be those for single men;

That there shall never be more than two decks (properly there should be only one), occupied by emigrant passengers' berths, with sixteen feet of superficial space for each adult on the upper berth-deck, and twenty feet of such space on the lower berth-deck, with not more than two tiers of berths on each deck, the bottom of the lower tier being not less than eighteen inches above the deck, with not less than thirty inches between the two tiers, and between the upper tier and the ceiling of the compartment, to allow the occupants of the berths to sit upright;

That no solid partitions or bulkheads shall be placed in any steerage compartment to obstruct light and air; that the frame-work of the berths shall be of iron easily removable, that the compartment may be completely emptied and thoroughly cleansed after each passage; that a steam ventilating apparatus by aspiration shall be introduced into all emigrant vessels; and that all compartments occupied by passengers and crew shall be lighted by the incandescent electric light by night and day.

Second: As to the location and dimensions of hospi-

tals on board such vessels and the number of sick-berths for which provision should be made;

That the hospitals, or "sick-bays" on board emigrant passenger vessels shall be at the extreme after-part of the upper deck, thoroughly lighted and ventilated, with eighteen feet of superficial space for every fifty passengers, and not less than four sick-berths or hospital-cots for every hundred passengers.

Third: As to the number of medical officers proper for the maximum of emigrant passengers any vessel should be permitted to carry, being the maximum number able to be berthed with regard to health, cleanliness, and comfort:

That there should be one duly qualified medical officer for every two hundred and fifty passengers.

Fourth: As to the professional records which the senior medical officer of every such vessel should be required to keep, and his responsibility to the health authorities of the port of arrival for the truthful and professionally accurate statements of such records;

That the senior medical officer of every such vessel shall be required to keep (1) a List of Sick, recording in a bound book, in the order of their admission, and on a single line, the name, sex, age, birth-place, date of admission to treatment, date of death or discharge from treatment, disease, and such remarks as may be necessary to enable the inspecting medical officer at the port of arrival to have a clear and complete understanding of the case; and (2) a Medical Journal, in which each medical officer, when there are more than one, shall record the medical history, including symptoms and treatment, of every case, to be approved and signed by the senior medical officer at the close of the day's record; and such List of Sick and Medical Journal shall be submitted to the health authorities of the port of arrival, and the accuracy of the statements in such records shall be established by oath, and penalties for perjury shall be provided.

Fifth: As to the location and capacity of latrines for emigrant passengers:

That the latrines, shallow troughs with a continuous flow of salt-water, shall be on the upper deck under shelter, with two water-closet seats for every fifty passengers, with a proportionate number for women and children, in a separate locality near their own quarters, and inaccessible to men.

Sixth: As to the number of attendants provided for such passengers, and their duties as to policing and cleansing emigrants' quarters:

That there shall be not less than one berth deck attendant for every fifty passengers, female attendants in the same proportion being exclusively assigned to the quarters for women and children;

That the berth-decks shall be thoroughly cleansed every morning by the attendants, never wetted in rainy or damp weather, when they shall be scraped, swept, and freshly sanded, and in pleasant weather washed with hot water and quickly dried, the passengers being sent on deck during the operation;

That the berth-deck attendants shall be on duty night and day in rotation, by regular sea-watches, and the attendants on watch be required to remove the dejecta of sea-sick passengers without delay; and that benches and mess-tables shall be provided and the passengers' food be distributed by the berth-deck attendants, who shall take away all unused food, and carry the dishes to the pantry.

Seventh: As to additional provisions for the personal health, cleanliness, and comfort of emigrant passengers:

That wash-rooms under cover, with basins supplied with running water, shall be provided on the upper deck, those for men to be separate from those intended for women and children;

That fresh water for drinking purposes shall be provided in each compartment; and,

That inexpensive mattresses, pillows, these to be serviceable as life-preservers, and blankets shall be provided for emigrant passengers, the mattresses to be destroyed after each passage, and the pillows and blankets to be steamed and washed before being again used.

While other suggestions as to sanitary provisions might appropriately be made, your Committee feel that those indicated are of such urgent necessity that they should be insisted upon and put into effect without delay.

All which is respectfully submitted.

Signed. ALBERT L. GIHON,
Medical Director, U. S. Navy, Chairman.

Health Officer of the Port of New York.

To Regulate the Practice of Medicine in Ohio.—The delegates of the Ohio societies in convention, December 21st, agreed to a bill with the following provisions: Section 4403. Within thirty (30) days after the passage of this Act, the Governor, by and with the advice and consent of the Senate, shall appoint a State Board of Medical Registration and Examination, consisting of seven (7) members, who shall be physicians in good standing in their profession. Representation shall be given to the different schools of practice in the State as nearly as possible in proportion to their numerical strength in the State; provided, however, that no one school of practice shall have a majority of the whole Board. The members of this Board shall be appointed for a term of seven years: for the terms of one, two, three, four, five, six, and seven years, respectively. Said Board shall organize by electing a President and Treasurer from among their number. They shall also elect a Secretary, who shall be a physician in good standing in his profession. The salary of the Secretary shall not exceed fifteen hundred dollars ($1,500) per annum, to be fixed by the Board, and necessary expenses in performing the duties of his office. The Treasurer shall be required to give a bond in the sum of ten thousand dollars ($10,000) approved by the Board. Members of the Board shall receive the sum of ten dollars ($10.00) per day for the time actually employed in the discharge of their duties and their necessary expenses pertaining thereto. The President and Secretary shall have the power to administer oaths. Said Board shall hold meetings at the Capital of this State on the first Tuesday of January, April, July, and October of each year, and such other meetings as said Board may from time to time appoint. Five (5) members shall constitute a quorum. Said Board shall keep a record of all the proceedings thereof, and also a record or register of all applicants for certificates as provided herein, together with the age of the applicant, time spent in the study of medicine, and the name and location of the institution granting said applicant the degree of Doctor of Medicine or Surgery. Said register shall also show whether such applicant was rejected or a certificate granted under this Act. Such books and register shall be prima facie evidence of all matters therein recorded. On and after the passage of this Act, no person shall practise Medicine, Surgery, or Midwifery, in any of its branches, in this State, unless such person has first complied with the requirements of this Act. If a graduate in Medicine or Surgery, he shall present his diploma to the Board for verification, registration, and certification as to its genuineness. Applicants presenting diplomas for verification under this Act shall accompany the same with the affidavit of the holder and applicant that he is the lawful possessor of the same, and that he is the person therein named, and giving his or her age and the time spent in the study of Medicine. Such affidavit may be taken before any person authorized to administer oaths under the laws of this State, and the same shall be attested under the hand and official seal of such officer; and any per-

son swearing falsely shall be deemed guilty of perjury and punished accordingly. Applicants may present their diplomas and affidavits as provided in this Act by letter or by proxy, and the Board shall issue its certificate the same as if the owner of the diploma was present. Any person not a graduate of a School of Medicine in good standing, as determined by this Board, who is a legal practitioner of medicine under the laws of the State in force at the time of the passage of this Act, shall be entitled to register and receive a certificate from said Board. Such applicant shall be required to furnish said Board an affidavit as hereinbefore provided, setting forth the length of time and the place or places during and at which he or she has engaged in the practice of Medicine or Surgery. Any person engaged in the practice of medicine in the State at the time of the passage of this Act, who is not a legal practitioner under the laws of the State in force at the time of the passage of this Act, or shall possess a diploma from a medical college not in good standing, shall present himself before the said Board of Registration and Examination, and submit to such examination as the Board may require. The fee paid to the State Board for the certificate shall be five dollars ($5.00). For the examination of applicants desiring to practise as provided herein, the fee shall be twenty-five dollars ($25.00). The person receiving a certificate to practise medicine or surgery from the State Board of Registration and Examination as herein provided, shall file the same, or a certified copy thereof, with the Probate Judge of the County in which he or she resides, and said Probate Judge shall file said certificate or copy thereof. Said Probate Judge shall each year furnish to the Secretary of the State Board of Registration and Examination a list of all certificates on file in his office. In case the holder of a certificate shall move into another County of the State, he or she shall procure from the Probate Judge of the County, a certified copy of said certificate, and file the same with the Probate Judge of the County to which he or she shall so remove. The Probate Judge of the County shall receive for the recording of such certificate, the sum of fifty (50) cents each to be paid by the holder thereof. Said Board of Registration and Examination may refuse to grant a certificate to any person who has been convicted of a felony, and may, by an affirmative vote of not less than five members of the Board, revoke a certificate already issued, for the same cause. Every person practising Midwifery in the State, on the passage of this Act, shall, within ninety (90) days thereafter, register with the Probate Judge of the County in which she resides, and shall pay a fee of five dollars and fifty cents ($5.50). Said Probate Judge shall issue a certificate to the one so registering, which shall entitle the holder to practice Midwifery in the County in which said certificate is issued. The Probate Judge shall annually, on the first Monday in January, make returns to the Secretary of the State Board of Registration and Examination of all such certificates on record in his office. All persons beginning hereafter the practice of Midwifery in this State, shall submit to an examination in Midwifery, and if such examination is satisfactory, the State Board of Registration shall, upon the receipt of ten dollars ($10.00) issue a certificate, which certificate shall be registered with the Probate Judge. The certificate granted to practice Midwifery shall not give the holder the right to perform version, or treat breach or face presentation, or do any obstetric operation requiring instruments, or to treat any other abnormal condition except in emergencies. Any person practising Medicine or Surgery in this State, without having first complied with the provisions of this Act as herein provided, shall be deemed guilty of a misdemeanor, and upon conviction shall be fined not less than two hundred dollars ($200.00) nor more than five hundred dollars ($500.00), or be imprisoned in the County Jail not less than thirty (30) days nor more than one year, or both fined and imprisoned. Any person practising Midwifery within the State without first complying with the requirements of this Act, shall be deemed guilty of a misdemeanor, and upon conviction thereof, shall be fined not less than twenty-five dollars ($25.00) nor more than one hundred dollars ($100.00). Such fines, when collected, shall be paid one third to the person, corporation, or medical society making complaint or furnishing information, and one-third to the Poor Fund of the County, and one-third to the State Board of Registration and Examination. It shall be the duty of the Prosecuting Attorneys of the respective Counties to prosecute violations of this Act.

THE TREATMENT OF SYPHILIS WITH SULPHATE OF COPPER.

BY A. F. PRICE, M.D.,

SURGEON, U. S. N.

IN March, 1891, I was detailed a surgeon of the United States Training Ship Monongahela, and while serving on the ship I have had some experience in treating syphilis with sulphate of copper. The results are interesting, and I think worthy of consideration.

Some years ago I read a notice in the MEDICAL RECORD of the successful use of this salt in syphilis by some French physicians, and the following case caused me to commence its use.

C. G——, aged twenty-four, was exposed to contagion about the middle of July, 1891, and suffered successively with gonorrhœa, epididymitis, and syphilis. He was placed on the sick list on October 28th, in the secondary stage of syphilis, and was given the protiodide of mercury, gr. $\frac{1}{6}$, thrice daily. He had then psoriasis over the body and rheumatic pains. The usual lymphatic enlargements were also present. On November 1st the treatment was reinforced by a daily inunction of ʒ ss. of mercurial ointment. This was, however, speedily reduced, and on November 8th stopped entirely, as was also the mercurial pill, on account of a rather severe attack of salivation. By November 21st this had passed away and mercury was again given (blue mass, gr. j.; dried sulphate of iron, gr. ij., thrice daily). This resulted promptly in ptyalism, and was stopped on November 26th.

On December 5th mercury was again given in reduced dose (blue mass, gr. ss., with sulphate of iron). By December 15th signs of ptyalism again appeared. He had spongy and ulcerated gums and fetor. Iodide of potash, 30 grs. daily, was then given, but the mouth continued unhealthy and the general health was very poor.

On January 13, 1892, the local and general condition was not improved, and he was given sulphate of copper, gr. $\frac{1}{8}$ in solution with ten minims of tincture of chloride of iron. Improvement began at once, and in about a month (February 10th) the patient's condition was decidedly better. The mouth and throat were healthy, the eruption had nearly disappeared, and the induration and enlargement of the lymphatic glands was decreased. The dose of copper was increased and that of iron reduced until, on February 23d, he was taking $\frac{1}{4}$ gr. of copper and five minims of iron thrice daily. The health had so much improved that he appeared like a perfectly well and strong man.

The further history of the case is devoid of incident. The copper was further increased so that in March he was taking $\frac{1}{2}$ gr., and on April 6th $\frac{1}{1}$ gr. with about four minims tincture of iron. In June he took $\frac{1}{6}$ gr. of the copper with iron, three times a day, every alternate week.

He was transferred to a navy yard shortly after this in a condition of apparent perfect health. He was under treatment altogether for about nine months. The mucous patches, which were abundant and troublesome before, disappeared after the copper treatment was begun, and did not again appear while under my observation.

The following case was treated with copper and iron only. The treatment lasted nearly nine months:

C. D——, twenty-six years of age, contracted the primary sore on October 31, 1892, and on December 30th he came under treatment for the secondary eruption. He had the usual enlargements of the inguinal, epitrochlear, and sub-occipital glands. He was given copper, gr. $\frac{1}{6}$, with sulphate of iron, gr. ij., thrice daily in solution.

On January 9, 1893, the glandular enlargements had increased and become much harder. By February 8th a change had taken place in them, in that they were softer. The eruption was also fading.

On March 8th the glands were only slightly enlarged, and a light discoloration of the skin alone remained of the eruption.

On April 20th the same condition of the glands was noted. The copper was now increased to $\frac{1}{3}$ gr., with iron as before, thrice daily. This dose was continued afterward during the whole of the treatment. The general health was and continued to be excellent; there were no mucous patches, nor had there been any at any time. The hair came out a little early in the disease.

On September 15th the patient declined further treatment, believing it unnecessary. This was contrary to advice, as the inguinal and other glands were perceptibly enlarged and hardened. There was no other sign of disease. The medicine was omitted one day in each week through the treatment.

The following three cases cannot be considered satisfactory examples of the copper treatment. They are given as showing some of the difficulties and dangers connected with the treatment:

CASE I.—T. M——, aged twenty-seven, was exposed to the disease about January 1, 1893. The primary sore appeared in the latter part of February, and on April 5th the secondary eruption presented itself. There was a decided induration at the site of the primary sore, and the usual glandular condition was present. Copper was begun at this time in the dose of $\frac{1}{3}$ gr. thrice daily, with sulphate of iron. The medicine was omitted one day in the week.

On April 20th the glands were less distinct and the eruption fading. There were no mouth symptoms.

On May 1st the patient complained of numbness and some loss of power of upper lip and eyelids. The eruption was nearly gone. The medicine was continued in the same dose, but given only every other day. The curious symptoms of paralysis disappeared promptly with the less active treatment adopted. He was transferred from the ship and from my care on June 8th.

CASE II.—M. C——, aged twenty-seven, was of very slender build and in rather poor health. He was exposed to the disease about January 20, 1892. Secondary symptoms appeared April 8th. There were very marked glandular enlargements, and the primary sore, which was also much indurated, was very difficult to heal.

The copper treatment was begun late in March, before the secondary symptoms had appeared. The usual dose of gr. $\frac{1}{3}$ was given, but it proved to be too much for him, for on April 23d he was incapacitated for duty by general debility and rheumatic pains. He suffered with giddiness, prostration, and a weak and rapid pulse. The copper was reduced to gr. $\frac{1}{12}$ thrice daily, and the iodide of potash, 30 grs. daily, given with it for the rheumatic pain.

On May 6th he had regained his usual condition of health, and the copper was increased to gr. $\frac{1}{6}$, with iron. He did well with this dose, and by May 23d the erup-

tion had nearly faded away, and the specific enlargement of the lymphatic glands was decreased in size. On this date the copper was injudiciously increased to gr. $\frac{1}{2\frac{1}{6}}$ thrice daily. This produced the old symptoms of prostration, and on June 2d he was transferred to a naval hospital.

In the following case a serious complication caused the treatment to be abandoned.

Case III.—D. R——, aged thirty three, was exposed to contagion on February 18, 1893. The primary lesion appeared six weeks later. On May 3d the secondary symptoms appeared. The usual glandular symptoms were present, and there was slight sore throat. Copper was given in gr. $\frac{1}{3\frac{1}{0}}$ dose, with sulphate of iron, omitting the medicine one day in a week.

On May 9th my assistant, during his week on duty, changed the treatment to mercurials, giving first a calomel purge, and following it with mercurial inunctions daily, and gr. $\frac{1}{6}$ of the protiodide of mercury thrice daily. At the beginning of the next week (May 16th) the copper was again given in the smaller dose of gr. $\frac{1}{6\frac{1}{0}}$.

On June 4th the enlarged glands were smaller in size and the eruption pretty well faded away. There were no mouth symptoms. The hair had not fallen. A small node appeared on the back of the right hand, near the wrist. He had rather severe rheumatic pains also, for which pot. iodide was given and the copper treatment stopped.

On June 12th the copper was again begun in the usual dose of gr. $\frac{1}{3\frac{1}{0}}$. This was continued until July 4th, when specific iritis appeared in both eyes. The treatment was changed to a full mercurial course, and in a week or two the eyes had recovered. His subsequent treatment was blue mass and iron.

I have also tentatively employed this drug in several other cases of syphilis, in various stages of the disease. I consider that the following conclusions may be formulated as being probably true; although I do not consider that either the number of the cases or the circumstances attending some of them allow of positive deductions.

1. Copper exercises a specific action in syphilis, which is especially directed toward the lymphatic system. It is for this reason more radically curative than mercury.

2. It is slow in removing the skin symptoms of the secondary stage.

3. It prevents the development of mucous patches and throat symptoms.

4. It is a very active drug, and it is wise to omit its use one day in a week, and sometimes more frequently. The signs of its excessive and injurious action are first a voracious appetite, and this is rapidly followed, if the dose is not reduced or the drug temporarily discontinued, by prostration, giddiness, pallor, and a rapid and weak pulse.

5. The average dose of sulphate of copper is $\frac{1}{3\frac{1}{0}}$ of a grain thrice daily. It is better to give it with the sulphate of iron. It can be given either in pill or solution.

6. This dose is absolutely dangerous in cases of syphilitic cachexia. It produces at once excessive and alarming prostration. If a sufficiently small dose of the drug is given at first, a tolerance of it is gradually established, so that the average dose may in time be obtained.

I am inclined to think that in some cachectic cases as small a dose as the $\frac{1}{1\,0\,0\,0\,0}$ of a grain may be necessary, given once daily. The use of iron, arsenic, and iodide is also usually necessary in old syphilis.

Facial Erysipelas.—Azotate of crystallized aconitine, in doses of one-fiftieth of a milligramme, will often lessen the duration and relieve the pain of this distressing malady.

Sub-Gallate of Bismuth.—This remedy (dermatol) has been found to be, in ten-grain doses after meals, almost a specific in cases of purely functional dyspepsia and flatulence.—Flint.

CAISSON DISEASE.

By ANDREW H. SMITH, M.D.,

NEW YORK,

PHYSICIAN TO THE PRESBYTERIAN HOSPITAL; PROFESSOR OF CLINICAL MEDICINE POST-GRADUATE MEDICAL SCHOOL.

For some months a work has been going on by the aid of compressed air that has resulted in the presence of a number of victims of the caisson disease in the wards of the Presbyterian Hospital. I refer to the construction of a tunnel under the East River at the foot of Seventy second Street. This tunnel is designed for the passage of gas mains from gas works that are to be erected on the Long Island shore. The tunnel is at such a depth below the surface of the river that the pressure required to keep out the water is about forty-two pounds to the square inch. This pressure is sufficient to produce typical cases of the disease. Up to the present time, of twenty-one cases admitted to the hospital there have been two deaths, and one case of complete paraplegia from which there is little prospect of entire recovery.

These cases possess a peculiar interest for me from the fact that, twenty-two years ago, I had the opportunity of studying this singular disease on a somewhat extensive scale, while physician to the Brooklyn Bridge Company during the sinking of the New York caisson. Viewed from the present stand-point, however, the observations of that period were defective, in that some phenomena, in relation to the nervous system especially, with which we are now familiar were then but imperfectly understood.

Those who have not given attention to this subject will obtain a good idea of the disease in its full development from the following case-history, taken from the records of the Presbyterian Hospital.

Patrick K——, aged twenty-nine, single; Irishman; miner. Family history: Negative. Previous personal history: Rheumatism, eight years ago; chills and fever, one year ago; acute gonorrhœa, three weeks ago; hard drinker for last ten years. Present attack: For the last eight years he has been working in tunnels under compressed air, but has never experienced any trouble from his work before. Day before yesterday, July 4th, he got "full." Yesterday he went to work again, and went into the caisson, did his work, and came out with the other men. Almost directly upon coming out he began to feel "nervous," had some difficulty in speaking, and some pain in the abdomen. He took several drinks of whiskey, but in about ten minutes he noticed that his legs were growing numb and unable to support him. He could feel his legs when they were touched, and he had no pain in them. In about twenty minutes more his legs were completely paralyzed. In this condition he was brought to the Presbyterian Hospital July 6, 1893.

His physical examination showed some râles over the lower lobe of the right lung behind. Other viscera normal. He has complete loss of power in both lower extremities, with diminished power in the lower trunk muscles. Muscular sense preserved. Sensation to pain or touch is lost. Patella reflexes absent. On account of his general condition he was ordered strychnine sulphate, gr. $\frac{1}{3\frac{1}{0}}$ t.i.d., and he was also given extr. ergot, fl. 3 j., every four hours, and put on fluid diet. He developed almost immediately retention of urine with overflow, the daily quantity of urine secreted by the kidneys being from eight to ten ounces, specific gravity 1.017, alkaline, loaded with phosphates and pus from his gonorrhœa. He was therefore catheterized at short intervals and his paralyzed bladder irrigated daily with one-fourth of one per cent. creolin solution. As the disease seemed likely to be a long one and the chance of bed-sores great, he was placed on a water-bed. On July 7th it was found that blisters were developing on various portions of his body. His abdominal pain was partly relieved by morphine. It was found that he had more or less paralysis of the intestines, his bowels moving only under the stimulus of large doses of calomel and salts, the tympanites being relieved somewhat by the introduction of the rectal tube.

On the 11th his temperature went up to 103.4° F., declining to normal in a few days; due apparently to some dry pleurisy on the right side, plainly heard.

On the morning of the 14th it was noticed that he could move slightly the first and second toe of the right foot, but nothing else in his lower extremities.

On the 30th he can bend the right knee somewhat and the trunk muscles are stronger, as he moves his body more easily.

To keep up the nutrition of the muscles, faradism is used daily. The bladder is beginning to show signs of returning power. The sphincter ani is still completely paralyzed.

On August 18th he is moving his two toes, his knees, and ankles.

By September 8th the bladder had regained somewhat its tone, the amount of urine secreted was nearly normal and negative in quality. He is off his water-bed in a wheel-chair for a few minutes each day.

On September 3d he is able to move a few more toes. The extensor paralysis is still complete.

On September 14th the area of anæsthesia is as follows: cremasteric reflex present. During all this time no contractures have taken place in the muscles moving the foot. Sensation to heat and cold about normal; partial anæsthesia from lower portion of thorax to umbilical line; complete anæsthesia below that level.

During October his improvement was steady, though slow. The bladder continued improving. The bowels, however, did not keep pace with the rest, obstinate constipation being a prominent symptom. Sensation is gradually returning to the anæsthetic area above. As soon as his strength was equal to it, an attempt was made to have him make some use of his legs by means of the walking-machine. When making use of this machine his toes drag clumsily on the floor, inco-ordination of the muscles of the leg being almost complete, various motions following one another before the legs could be brought to the front. By means of the machine, however, gradual improvement was noticed, the tonicity of the leg and calf-muscles improving also.

At the present time, December 6th, there is practically no anæsthesia of the body. His urine is passed in a "duck" which he has with him attached around his waist or held between his legs when sitting. There are times when the urine accumulates in the bladder, but never for more than an hour at a time. But when the desire to urinate comes on he is still unable to control the flow. The bowels are controlled only to the extent that when the desire to defecate comes on he can reach the closet just in time. His appetite is good, general nutrition fair.

This case illustrates most of the features of the disease. Pain is the most common of these, and is rarely absent, although in exceptional cases paralysis may occur without it. The pain is most common in the lower extremities, and especially in the knees and hips. It is often felt in the lumbar and sacral regions, and is aggravated by the erect position. The resulting stooping posture gives rise to the common designation of the disease as "The Bend," or "The Grecian Bend," alluding to the fashionable stoop in walking common among women at the time when the Brooklyn Bridge was being built. Pain in the epigastrium is very common, and is apt to be associated with nausea and vomiting. The pain is often of the most intolerable severity, completely subduing men indifferent to minor suffering. It is felt not only in the joints, but also in the shafts of the long bones. It is sometimes accompanied by considerable tenderness on pressure, at other times pressure seems to give a measure of relief. The pain is rarely continuous in the same degree of severity, there are lulls followed by exacerbations. The onset is sometimes gradual, at other times it is almost as sudden as the fulgurating pains of tabes.

The reflexes are generally either exaggerated or abolished. There is no uniformity in this respect. Sometimes they are exaggerated at first, and afterward diminished or lost, and *vice versa*. During paralysis the knee-jerk is commonly increased. Paralysis more or less extensive and persistent occurs in a considerable proportion of the cases. It more generally affects the lower extremities, though the arms are not exempt. Sometimes an arm and a leg are affected. The paralysis may be absolute, or there may be simply a slight and transient paresis. When the lower extremities are attacked the bladder is usually involved, and sometimes the sphincter ani.

The paralysis is of sensation as well as motion, but it does not bring relief to previously existing pain. It is common to see a patient suffering agony in his legs, and yet insensible to the prick of a pin or the contact of a hot test-tube. The paralysis, even in severe cases, is rarely as persistent as in the case of Kelly which I have just read. Usually it passes off in a few days, or in a few weeks at the longest. In rare instances it is permanent.

Symptoms of a transient character connected with disturbance of the cerebral circulation are often observed. Such are headache, giddiness, double vision, syncope, slight confusion of intellect, etc. But these cerebral disturbances may take a very serious form, and coma is usually observed in cases that prove fatal.

In some cases there is an extensive mottling of the skin. The wine-colored stains may be rubbed away in some places, and do not return, in other places they represent a true ecchymosis, and cannot be effaced.

The duration of the case is not necessarily in proportion to its apparent severity. Cases marked by extreme pain may recover entirely in the course of a few days, or even a few hours, and a marked degree of paralysis may be of equally short duration.

The average time in hospital, excluding the case marked by persistent hemiplegia which I have already cited, was, for the twenty-one cases received into the Presbyterian Hospital, three days. Among these cases there were two deaths.

In every case in which an autopsy has been made there has been found evidences of cerebral or spinal congestion, and the mode of death is generally such as to point to a lesion of the brain or cord. In one case at the Brooklyn Bridge sudden death by asphyxia occurred after the patient had walked a few rods from the pier. It seemed probable that an extravasation had taken place into the medulla. The body was taken to the morgue, but unfortunately the autopsy did not include an examination of the spinal canal. The lungs were intensely congested.

In another case the brain was in a healthy condition, but the cord was congested, and opposite the two lower dorsal vertebræ there was an extensive effusion of blood compressing the cord.

Congestion may be found in other localities, especially in the liver and spleen. Spots of extravasated blood have been found in the kidneys. The gastric, intestinal, and vesical mucous membranes are sometimes congested and even marked with ecchymotic spots.

The pathology of this affection is intimately connected with the congestions already described, and especially with the congestion of the brain and spinal cord, and the cavities of the long bones. Much discussion has arisen as to the mechanism of these congestions. Francois suggested that they might be due to the liberation of bubbles of air from the blood when the pressure was reduced, the bubbles acting as emboli and obstructing the vessels. But this would not explain the peculiar distribution of the congestions. Furthermore, Paul Bert, who reasserts the theory of Francois, with the difference that he claims that the bubbles are of nitrogen instead of air, states, as the results of his experiments upon animals, that, with a pressure of five atmospheres three minutes allowed for the return to the normal pressure will be found to insure the escape of the gas through the lungs as rapidly as it is disengaged from the blood, and thus prevent the formation of gas emboli. But numerous cases of the caisson disease have occurred when the pressure did not exceed two at-

mospheres, and when six to eight minutes were occupied in equalizing the pressure. According to Bert's experiments, no possible danger of the formation of gas bubbles could occur under these conditions.

Bert's theory is opposed to the fact that a large degree of immunity from danger is acquired by exposure to the compressed air when the pressure is light, and continuing as the pressure increases.[1] The presence of bubbles of gas in the vessels is a condition which the system could never learn to tolerate by frequency of repetition.

Dr. Jaminet, who had charge of the men in the caissons at the St. Louis Bridge, attributes all the phenomena of the disease to exhaustion from excessive tissue-change brought about by the abnormal absorption of oxygen under the increased pressure. But this is obviously insufficent to account for the anatomical conditions found after death, and affords no explanation of the disastrous effects of too rapid reduction of the pressure in returning to the open air from the caisson.

A careful study of the subject led me to the conviction that the essential phenomena of the caisson disease depend upon the displacement of blood from the vessels which are exposed to the direct action of the pressure to those which, from their situation, are protected from such direct action. For example, the vessels of the skin feel the pressure most directly, and are emptied into those of the interior, as is shown by the pallor of the surface, which is very marked while in the caisson. The fingers, being exposed to the pressure on all sides, are emptied of blood and become white and shrivelled, as if the skin were too large for them. In like manner, wherever the tissues are soft and compressible, the blood is forced out of them and into localities where the tissues are protected from pressure by the density of the surrounding structure. In this way the liver and kidneys get more than their normal supply of blood. But this protection from direct pressure is most complete in the bony cavities, such as the cranium, the spinal canal, and the shafts of the large bones. In these cavities equilibrium of pressure can be established only by afflux of blood, and it is inevitable that they receive more than the usual amount, more, in fact, than any other part of the body, as no other part is so perfectly excluded from the general effect of the increased pressure.

It becomes apparent, therefore, that after a brief sojourn in the compressed air, the system is no longer supplied with blood in accordance with the physiological requirements of the several organs, but in accordance with unnatural physical conditions imposed upon it from without, and having no reference to the normal calibre of the vessels. In a word, the vaso-motor function is entirely superseded, and the muscular coat of the vessels thrown completely out of use. The vessels are as passive as the water-pipes in a house. It is plain that the longer this state of things continues the more complete will be the suspension of the normal vascular action, and the more difficult the resumption of the natural blood distribution when the abnormal pressure is removed. The vessels of the brain and cord having been the most perfectly protected from the direct pressure, will be the most distended, and the most helpless to relieve themselves. Blood having been forced into the cranium and spinal canal, with a pressure of thirty or forty pounds, has continued to circulate, it is true, but only because the whole vascular system was subjected to the same pressure. But now there is a sudden removal of the pressure from the soft parts, resulting in a great increase in the vascular area and a relatively low tension. The vessels in the bony cavities do not readily participate in this changed condition, for they have been overdistended instead of compressed, and their muscular structure is in a state of paresis, if not of paralysis. The blood-currents, therefore will find these localities already passively filled, and will pass them by until such time as the returning contractility brings their vessels in normal relations with the general vascular system. But meanwhile the slowing of the current, or perhaps actual stasis, has brought about more or less serious and permanent results. Thrombi may have formed, affording material perhaps for emboli at more distant points.

In short, conditions are produced in the first moments of lower pressure which not only may remain, but which may result in progressive hindrances to the circulation, showing their effects after the lapse of several hours. Hence we see many cases presenting successive phenomena, such as pain in one place followed by paralysis in another, or paralysis affecting first a leg and then an arm, and succeeded by pain in the abdomen or back.

In this connection the influence of trophic cells in the brain or cord upon peripheral nutrition is not to be lost sight of.

I have already referred to the comparative immunity which comes with daily exposure to gradually increasing pressure. This is readily explainable by assuming a gradually acquired adaptation on the part of the vessels to changes in the amount of their contents. This would be only an extension of the physiological principle by which the supply of blood to organs with an intermittent function is increased during the periods of activity and lessened when the function is in abeyance.

The ideal treatment of the disease, when first manifested, is the re-exposure of the patient to compressed air. From the first this has been recognized as giving complete relief. But the difficulty of returning the patient into the caisson led me to suggest that a small air-tight chamber should be provided, in an accessible situation, into which compressed air from the caisson could be conducted, and in which the patient could remain until relieved. The pressure was then to be reduced by very slow degrees, several hours being occupied, if need be, in the process.

This suggestion was acted upon by the North River Tunnel Company, and the superintendent informed me that the success was complete.

Of course this treatment would be of no avail after secondary changes had taken place.

Aside from this expedient the treatment will depend upon the severity of the case. Pain, if severe, had better be met at once by an efficient dose of morphine, given by hypodermic injection. As the duration of these severe pains is usually short, it is entirely practicable in most cases to carry the patient through with morphine, keeping him perfectly comfortable until the circulation has had time to become re-established in its normal course.

Vomiting without pain is alleviated by sinapisms and by swallowing bits of ice. When associated with epigastric pain a hypodermic injection of morphine will relieve both.

Acting upon my view as to the pathology of the disease I have employed ergot freely with the expectation of rousing the vaso-motor system into greater activity, and by increasing the vascular tension, and with it the velocity and force of the circulation, lessening the tendency to stasis. The result seems to have justified my expectation. In numerous instances ergot administered at the beginning has apparently cut short the attack. The foreman at the Brooklyn Bridge was supplied with both morphine and ergot for immediate use in the absence of the physician, and his conviction, from his experience, was that ergot acted more satisfactorily than morphine. Of course, in either case the administration was by the mouth. In all the cases in my service at the Presbyterian Hospital ergot has been used, and generally with apparent benefit.

Local applications, employed with due regard to the tenderness of the muscles, which is often extreme, seem in many instances to be comforting to the patient.

[1] Of the men who began with the work at the Brooklyn Bridge, comparatively few suffered when the pressure became greater, while of those who began later a large proportion were attacked. In the East River tunnel, the work proceeding horizontally at a uniform depth, the pressure has been at the maximum from the beginning, and the men, not having the advantage of becoming accustomed to a gradually increasing pressure, are suffering much more generally and more severely than was the case at the bridge. It is true, however, that the pressure is greater in the tunnel.

When paralysis occurs it is to be treated on general principles. Cases which have lasted for months are not necessarily hopeless, though improvement may be extremely slow. I have never seen a patient recover after the supervention of complete coma.[1]

But more important than treatment is prophylaxis. I have found that persons with a tendency to obesity are much more liable to the affection than those of a more slender build. This is probably due to the greater bulk of fluids in the body liable to displacement by the compression of the soft parts. Corpulent persons should therefore be excluded from the caisson.

Intemperate habits also predispose to the disease. Probably this is due to the vascular changes resulting from chronic alcoholism, on the one hand, and to the acute congestions, on the other hand, incident to a recent debauch. Men seasoned to the work, and who have all along resisted the effects of the pressure, have succumbed on the first return to the caisson after a drunken orgie. Men with a pronounced alcoholic habit should therefore be refused employment when the pressure is considerable. Newness to the work, as already stated, increases greatly the danger of attack. For this reason men beginning work after the pressure has reached twenty-five or thirty pounds, should not be permitted at first to remain below more than two hours at a time, the hours being gradually increased as the person becomes seasoned to the work.

But most important of all preventive measures is limiting the duration of the shifts in proportion to the increase of pressure, and giving abundant time for "locking out." With a pressure of forty pounds the men should not remain below more than two hours at a time, and four hours should constitute a day's work. The "locking out" should occupy at least five minutes for each atmosphere of additional pressure. The escape-valve in the lock should be gauged so as to insure this result.

It is also important that the effort of climbing to the surface should not be made while the system is adapting itself to the reduced pressure. In other words, the lock should be at the top of the man-shaft instead of at the bottom. The ascent is then made in the compressed air instead of in the relatively attenuated atmosphere without. When this position of the lock is impracticable, a lift should be provided to take the men from the lock to the surface.

A Unique Sanitary Building.—In Yokohama a unique building has recently been constructed by Dr. W. Van der Heyden. The walls are of boxes of glass arranged in brick fashion and filled with a solution of alum, which allows light to pass but intercepts certain heat-rays. These boxes, which have now resisted during one year and a half the influence of cold and heat, shocks and earthquakes, are resting on cast-iron supports. The necessary gaps between two rows are filled with felt and then covered with boards. A series of the boxes above each other and next to one another, with as little space between as possible, and this space filled with felt, form the outside walls of the house; the roof, which is flat and is supported by the cast-iron pillars which carry the boxes, can be made in exactly the same mould. In the house, glass panes pressed against each other, but with strips of rubber between them, form the horizontal ceiling; above this a thick layer of ashes rests, whereupon is a light frame-work of wood covered over with cement. This, of course, makes the roof not translucent, but it defends the roof well against radiant heat, and being made of bad conducting material, the heat of the interior is not lost; the four walls being totally translucent, there is more light than in any other description of dwelling. Special arrangements provide for ventilation and drainage.

[1] Since the above was written a man was brought to the Presbyterian Hospital in a comatose condition, from which he rallied and made a good recovery.

NOTES ON THE CAISSON DISEASE.[1]

By W. GILMAN THOMPSON, M.D.,

NEW YORK.

The caisson disease is of peculiar interest as a malady incident to modern civilization, in which definite symptoms are directly produced by purely physical, *i.e.*, mechanical, causes, acting primarily through the circulation and through this means upon the central nervous system. The respiratory mechanism is also affected, but not in a manner to occasion the symptoms of the disease, except in so far as any variation in normal respiration reacts upon the circulation. In an atmosphere of compressed air the oxygen tension is increased, and the rate of respiration is somewhat slowed, but while it may be easy for the blood to obtain abundant oxygen, it is also more difficult for the carbon dioxide to be eliminated from the lungs against increased atmospheric pressure. As a result, with very high pressure animals die with convulsions, asphyxiated by retention of their own carbon dioxide. In the caisson disease, on the contrary, we have present a series of symptoms the most prominent and constant of which are referable to the inferior portion of the spinal cord; these are—pain along the peripheral nerves and the joints, especially of the lower extremities, various sensory disturbances, altered reflexes, interferences with the normal processes of micturition and defecation, and paralyses of the extremities. In a series of experiments made at the Loomis Laboratory, which I reported four years ago,[2] performed with the object of determining the effect on animals of inhaling atmospheres of pure oxygen under very high pressures, the symptoms of the caisson disease were not present. In these experiments a monkey withstood the pressure of four and one-half atmospheres of pure oxygen for three-quarters of an hour, the only effect being a very slight convulsion from too suddenly lowering the pressure. Monkeys, cats, dogs, and pigeons were all kept under four atmospheres of pure oxygen, as well as of simple compressed air, for an hour and a half, without any paralytic or sensory symptoms, although slight convulsions sometimes occurred when the pressure was altered too suddenly. A dog weighing 22½ pounds withstood for some time a pressure of eight atmospheres of common air before evincing any discomfort at all. He then had a slight convulsion, but on coming out of the compression tank he appeared normal and lively. Another animal withstood a pressure of nearly five atmospheres of air over half an hour without showing any symptoms of discomfort whatever, and subsequently remained three and three-fourths hours in two atmospheres of pure oxygen without symptoms. It does not appear from these experiments that single exposures to pressures much greater than those to which workmen in compressed air are subjected (*i.e.*, two and one-half to three and one-half or four atmospheres) are capable of producing in animals any of the symptoms of the disease in question. It should be borne in mind, moreover, that the severe labor which they undertake in the shaft, in digging, crushing stones, etc., is itself somewhat exhausting to the circulation. They become fatigued and eager to get out at the end of their "shift," and come out far too quickly—often in five or ten minutes. It is the suddenness of the change back to normal atmospheric pressure which is the disturbing element, rather than the continuance in the compressed air of the caisson. The effect is somewhat analogous to that produced on the circulation by a too rapid ascent in a balloon into rarefied air, and by sudden extreme hemorrhage. I have seen five cases of caisson disease, one or two of which are here reported in full, and to these I may add one more which occurred in the service of Dr. A. Brayton Ball, at the New York Hospital, and to which he has kindly allowed me to refer. One of these five cases has just been reported in the collection presented

[1] Read at the meeting of the Practitioners' Society, January 5, 1894.

[2] A paper read at the New York Academy of Medicine, MEDICAL RECORD, July 6, 1889, vol. xxxvi., No. 1, p. 1

by Dr. Smith. Another case, P. C——, was that of a laborer in the Hudson River caisson who entered the New York Hospital in September, 1890. He was a robust man, of good habits and constitution, thirty-eight years of age, and a very moderate drinker. He had worked for many years previously in caissons. He often had severe pains in the extremities after leaving the caisson, but had never before suffered from paralysis. Six days before admission to the hospital, and after leaving his work, he suddenly lost all muscular power and sensation in both legs. This condition lasted a day or two and slowly improved, when he found himself unable to micturate, and for this difficulty sought relief in the hospital. On admission there were no constitutional symptoms; pulse, respiration, and temperature were normal, and the various viscera appeared normal. The urine contained five per cent. of albumin and considerable pus. The patient was unable to walk from loss of power in the muscles of both legs, but he could move the feet and toes. Sensation was considerably diminished in both legs, especially in the left, but was normal elsewhere. The patellar reflexes were slightly exaggerated. There was no ankle clonus. No local tenderness over the spine or peripheral nerves. There was no pain at any time such as had been present before the paralysis. The hands and arms were not affected. Catheterization was necessary, as there was complete retention of urine. The patient was given strychnine and ergot, the bladder was irrigated with boric acid solution, and galvanism was applied to the legs. After three days of this treatment, with rest in bed, there was considerable improvement, and increase in power in both legs. At the end of a week the patient could pass his urine voluntarily, although still with some difficulty. He was allowed to rise and was able with assistance to walk a few steps. After sixteen days he walked easily; only a little weakness and uncertainty in gait remained, and he was permitted to go home. Sensation and micturition were normal. In this case, after three weeks, cure resulted of complete paralysis of the legs and bladder.

Case of J. H——, laborer, aged thirty-three years; is a moderate drinker. Admitted to the Presbyterian Hospital August 8, 1893. For the past fourteen years, on and off, the patient has worked under compressed air, but never suffered from it in any way until five or six years ago, when he had several slight attacks of anæsthesia and paresis in the extremities, coming on immediately after leaving the caisson and lasting several hours at a time. He said that similar attacks with vertigo, chilliness, and deafness, are of such common occurrence among his fellow-workmen that they pay little heed to them, so long as they are not actually incapacitated from work. The night before his admission to the hospital, and about fifteen minutes after leaving the caisson in the East River where he had been at work under four atmospheres of pressure, and after coming out of the single lock very suddenly (in about five minutes), pains of a tingling and lancinating character began in the right leg, and he found himself unable to walk. An hour later the same symptoms appeared in the left leg, and continued. Micturition and defecation were unaffected. On admission, the pulse, respiration, and temperature were normal. Urine normal. The man was of exceedingly good physique. He retained some voluntary power and co-ordination in the legs, but was wholly unable to stand. The patellar reflexes were exaggerated, and there was some tenderness along the course of the nerves in both legs. The hands and arms were normal. The patient was given strychnine and ergot and a cathartic, and the faradic current was applied to the legs. He asked for the latter, as he said it had relieved him very promptly before. Very rapid improvement followed, and on the fourth day the paralysis had entirely disappeared.

In two more cases, which came under my observation several years ago, the symptoms were almost identical with those of the preceding case and recovery was complete.

The following notes are abstracted from the history of a patient who entered the New York Hospital, in the service of Dr. Ball, in July, 1890. The patient was a laborer, twenty-five years old, a moderate drinker. Six months previous to admission to the hospital he began digging in a caisson, working most of the time under a pressure of four atmospheres. After two months of this labor he had frequent attacks of sharp pains in the limbs, and especially in the knees and elbows, which continued for three weeks, but he kept on with his work. After three months he was suddenly seized with paralysis of both legs and the left arm, and the pains in these limbs became very severe. He also had total deafness and dull pains in the head and abdomen, accompanied by a severe attack of vomiting, with marked weakness and prostration.

The deafness and paralysis lasted about three days, and then gradually wore off. Three weeks later he had completely recovered. He returned to work, and after that time he had frequent headache and pains in the limbs, but the paralysis did not return. For the week previous to admission he had complained of difficult micturition, constipation, and pricking and itching sensations in the arms and shoulders. No girdle pains were noticed. He entered the hospital to be relieved of his inability to urinate. He was given cathartics, strychnine, boric acid, and hot baths. Three days later he appeared much better, and was allowed to get up, when a slight relapse occurred. After further treatment and rest in bed, he was discharged cured on the twelfth day.

Since in all instances of caisson disease the main danger lies in the too rapid change of pressure, especially its diminution, one cannot condemn too strongly the practice of allowing the workmen to leave the caisson very rapidly. For reasons of economy but one "lock" is sometimes afforded between the atmosphere and the caisson, and the men are allowed to hurry in and out at a rate which implies criminal negligence. Where four atmospheres of pressure are employed, there should be at least three "locks" with graded air-pressure, and fully three-quarters of an hour should be consumed in entering or leaving the caisson, instead of five or ten minutes. The progressive character of the symptoms should be a warning to those who have had a first attack that they cannot with safety continue to work under the same conditions.

CONCERNING THE CUSTOM OF ABUSING "THE ABUSE OF MEDICAL CHARITY"—A PROTEST.[1]

By J. WEST ROOSEVELT, M.D.,

LECTURER ON CLINICAL MEDICINE IN THE COLLEGE OF PHYSICIANS AND SURGEONS; VISITING PHYSICIAN TO BELLEVUE HOSPITAL; ATTENDING PHYSICIAN TO THE ROOSEVELT HOSPITAL, NEW YORK.

I FIND the following sentence in a paper written by Miss Octavia Hill, of London: "Impatience seems to me to be the curse of time; even our benevolence is in such frantic haste; we hurry even to seem to mend matters, and we make them tenfold worse, and some of us hardly care." Miss Hill is well known as a philanthropist whose life is devoted to practical charity. The words quoted are taken from a paper directed against indiscriminate and unwise schemes for benefiting the poor; the impatience she mentions is that shown in providing too easily obtained and injudiciously distributed aid. Is it not equally true of many attempts to reform existing abuses of charitable methods? It seems to me that almost all of the recently published criticisms upon, and tirades against, the administration of hospitals and dispensaries, in regard to the class of persons treated in these institutions, shows the same "frantic haste" of which the distinguished authoress complains. None can appreciate more clearly than I the serious evils which our system has brought about—none would more gladly second all well-conceived plans making for the diminution of the evils. Therefore I feel the great importance of conducting the campaign against

[1] Read before the Practitioners' Society, January 5, 1894.

them in a rational and efficient way; they should be attacked systematically and persistently with the best weapons obtainable. They should also be attacked upon the right grounds. The weapons to be used are arguments based upon facts, not fancy, and the broad general principle of public good is the only position from which a successful assault can be made. This paper is a protest against the present line of attack, which is frequently based upon unfounded assertions, and still more frequently is characterized by the narrowness of view of the critics and evident unfamiliarity with the conditions of the problem and the various plans which have from time to time been tried to lessen the evils complained of. As for the suggestions of most of the recent critics for bettering things—well, they are not likely to be adopted by any considerable number of institutions.

The trouble with most of those who discuss the subject is that there are several different stand-points from which it may be considered. None of these by itself is broad enough to base a fair judgment thereon: yet it is rare for the critics to regard more than one. Hence arises much confusion.

What I have called "the custom of abusing 'the abuse of medical charity'" is becoming very common. It is apparently impossible for the majority of people to study calmly, and write or speak without excitement about any matter which, although in noway affecting their reputation or characters as individuals, concerns seriously some of their pet theories, or touches their personal interests. The proper distribution and administration of medical charities concerns closely the pet theories of the laity and the personal interests of the profession. Probably these are the reasons for the extreme warmth of the discussions about the question, and for the marked tendency toward the introduction of personalities. Am I not justified in asserting that the tone of the professional criticisms has, especially of late, been more abusive than judicial; more violent than philosophical? It is neither dignified nor useful to indulge in tirades about some alleged wrong, without presenting at the same time the facts in the case complained of. Generalities are powerless against specific evils. Actual facts must be given. Moreover, any statements which are incorrect serve the more firmly to intrench the evils. Let an assertion be made which is perfectly true in all particular specifications save one—the whole force is weakened or even destroyed by the one error. Loose talking has done much to perpetuate the evils in our hospital and dispensary methods.

We should not cry out against the injury wrought by the dispensaries to struggling practitioners; neither should we talk about the benefits of these institutions to the cause of medical education. We should speak neither from the position of those who are injured nor those who benefit in our profession; we ought to look at the matter in a broader and more patriotic way. The benefit or harm to the whole community are the real things of importance. Individual wrongs are petty when compared to the good of the whole.

These charities unquestionably do much harm—how much is unknown. This fact should be constantly kept before the public. The problem of lessening the harm done is one of the most complex which humanitarians can face. Its solution requires careful study and long-continued experiment; it is not to be settled offhand. I know of no plan which has yet been tried which has done much to improve matters. There have been many suggested. Let us try now to treat the matter in a philosophical way, remembering the existence of the laws of political economy, and the limitations imposed by human nature upon every suggested method of relief. If we really wish to accomplish anything, there is no use of setting about it in a wrong way, and in more or less complete ignorance of what we are fighting with and what we are fighting for. It is by doctors that the problem must be solved, if it is to be solved. Let us set aside all bias and personal feeling, and proceed in a dignified manner to study the subject, and to express our views.

A SUCCESSFUL CASE OF PYLOROPLASTY.

By FRANCIS J. SHEPHERD, M.D., C.M.,

SURGEON TO THE MONTREAL GENERAL HOSPITAL.

The operation of pyloroplasty is of sufficiently recent origin, and the number of cases reported so comparatively few, that any fresh evidence as to its value will, no doubt, prove useful.

The operation, which was almost simultaneously conceived by Heincke, of Erlangen, and Mickulitz, is performed by cutting the anterior wall of the strictured pylorus and extending the incision about an inch toward the stomach, and the same distance in the direction of the duodenum. The straight incision in the long axis of the pylorus divides the stricture, and by retracting the margins of the wound on each side of the centre with tracula, and suturing the wound in a transverse direction, the contracted pylorus thus becomes the posterior wall of a new pylorus. The anterior wall of the new pylorus is made up of tissue taken partly from the anterior wall of the stomach and partly from the anterior wall of the duodenum.

The new portion of the pylorus is thus formed of perfectly healthy tissue, and relapses are therefore less likely to occur than after Loreta's operation of divulsion. This operation is in every way superior to Loreta's, it is much more scientific, and is applicable to all cases of non-malignant tumors. In Loreta's operation one is working in the dark, and the force necessarily used to produce enlargement of a greatly contracted pylorus, surrounded by a dense mass of cicatricial tissue, often produces serious results; death from shock and hemorrhage being not infrequent.

The operation of pyloroplasty is one of no great difficulty; in my case the retracting of the margins of the incision so as to make the wound a transverse one was somewhat difficult; there was so much cicatricial tissue and this tissue was so inelastic, that the duodenal and gastric incisions had to be prolonged before approximation could be accomplished, and even then the angles of the wound (which consisted of cicatricial tissue), had to have V-shaped pieces taken out to make the apposition perfect.

The patient was fed by the rectum for three days, and afterward carefully fed by the mouth; the recovery was uninterrupted.

Patient left hospital in four weeks, and when last seen, five months after operation, he had gained sixty pounds and said he had never felt better, his digestion troubling him not at all.

The following is the history of the case condensed from the hospital records:

R. B——, aged twenty-nine, farmer; native of Canada. Was admitted into the medical wards of the Montreal General Hospital, under Dr. G. Wilkins, July 10, 1893, suffering from vomiting and pain in the left side of the abdomen.

History.—Born and has always lived in the Province of Quebec. Has always been a teetotaller and does not use tobacco in any form. For the past fifteen years has suffered more or less from his stomach, having had frequent attacks of gastritis which have lasted from two weeks to two months. In the intervals never felt comfortable after eating, always experienced some pain and heaviness with eructation of gases. The last severe attack was three years ago, when he vomited a considerable quantity of blood and suffered very acute pain. The present attack commenced three months ago, since which time he has been unable to work: like the others it was preceded by pain and eructation of gas, then there was pyrosis, and afterward severe vomiting. At the beginning of the attack the patient was able to eat and retain a small amount of solid food, but later on everything taken was vomited. The vomited matter consisted of greenish material and some mucus, and frequently the vomit looked like coffee grounds. The pain usually came on two or three hours after eating.

During his present illness he has lost much flesh, weigh-

ing now only one hundred and twenty pounds, where formerly he weighed one hundred and seventy-five. Patient has been able to take only liquid food, and this, he says, appears to stay in his stomach, and relief does not come until vomiting is set up and the contents of the stomach evacuated.

Present Condition.—A young man, about thirty, tall, and much emaciated; muscles flabby, skin of a subicteroid hue, tongue coated with a white fur. On palpation of the abdomen no tumor can be made out, but the epigastric region is excessively tender, and the whole abdomen appears to be occupied by a distended and dilated stomach. Soon after entrance he vomited forty-three ounces of a brownish, sour-smelling fluid which on examination was found to contain free acid and sarcinæ. Urine, specific gravity, 1.013. No albumin or sugar.

Dr. Wilkins ordered the stomach to be washed out and this gave much relief.

Diagnosis.—Dilated stomach due to stenosis of pylorus, probably non-malignant. Dr. Wilkins thinking the case suitable for operation, and the patient consenting, transferred him to the surgical side under Dr. Shepherd. Three days before operation the patient's stomach was washed out daily with a warm solution of boracic acid, and the morning of the operation the washing was most thoroughly performed. Operation performed July 28, 1893.

After thorough cleansing of the parts, an incision four inches long was made above the umbilicus in the median line, and the stomach immediately brought into view, the pylorus was drawn out and found to be surrounded by a dense mass of hard tissue the size of a small egg, the anterior surface being marked by a stellate scar. An incision was made into the stomach near the pylorus and the condition of the opening examined; a large mass was seen below the pyloric opening, and this appeared excavated as if it had been the base of an old ulcer; it bled freely on touching it; the excavation would probably lodge a marble. The pyloric opening would not admit the tip of the operator's little finger, and admitted with difficulty a small grooved director.

The incision in the stomach was now extended through the stenosed pylorus and into the healthy duodenal tissue beyond, and thus the intestinal canal was laid open to the extent of two and a half inches. The edges of the incision were now seized about the centre with tenacula and retracted, this making the wound a transverse one. In this way healthy stomach tissue was approximated to healthy duodenum, the angles of the wound being the old cicatricial tissue in front of the pylorus, which was now replaced by the healthy tissue above referred to. To bring the angles of the wound together it was necessary to remove a V-shaped piece of the cicatricial tissue (which cut like grizzle) and to enlarge the original wound in the duodenum and stomach. The suturing was in two rows and commenced at each angle, the central part being sutured last. The suturing was a somewhat difficult proceeding, for the tissue at the angles being cicatricial, the fine interrupted silk sutures easily cut through; a superficial row of Lembert's sutures was more easily placed. The wound being now completely closed, the sponge and gauze were removed, the pylorus replaced, and the abdominal wound sutured with a deep-buried row of silk and a superficial row of silkworm-gut sutures.

The patient stood the operation well, and left the operating-room with a good pulse. Soon after removal to his ward a beef-tea enema was administered.

July 29th.—Temperature, 98⅗° F.; pulse, 100. No vomiting or pain. Peptonized milk enemata administered every four hours.

July 30th.—Temperature, 99⅖° F.; pulse, 100. Given a very little weak brandy and water by the mouth; enemata still continued.

August 1st.—Temperature, 99° F.; pulse, 80. Enemata discontinued; given barley-water by mouth every two hours.

After this he took beef-tea and milk by mouth, the administration being in small quantities and carefully supervised by the house surgeon, who gradually increased the amount of nourishment taken. On the tenth day he had a rise of temperature and severe pain, due, he admitted, to having eaten some rich fruit-cake given him by another patient. After this everything went on well. The patient rapidly gaining flesh and strength, got up at the end of the third week, and was discharged on August 31st. He was shown to the Montreal Medico-Chirurgical Society on November 17, 1893, when he looked in perfect health, weighing one hundred and eighty pounds, and saying he was as well as ever he was, nothing now disagreeing with him.

MONTREAL, December 18, 1893.

Clinical Department.

SARCOMA OF THE TONSIL—PATIENT EIGHTY-NINE YEARS OF AGE—OPERATION—CURE.

BY CLINTON WAGNER, M.D.,

SENIOR SURGEON METROPOLITAN THROAT HOSPITAL.

MRS. F——, aged eighty-nine, applied for treatment at the Metropolitan Throat Hospital. She stated that for several months before consulting me she had felt a swelling or lump in her throat, which seemed to her to be rapidly increasing in size.

An examination revealed a growth on the right tonsil which entirely filled the right side of the fauces, extending inward to the uvula which it pushed aside, pressed the soft palate upward and backward, and extended downward into the pharynx to the base of the tongue; it pressed also against the anterior column of the palate, forcing it forward and rendering it quite tense. In color it was a dark, dull, purplish red, resembling somewhat frozen flesh.

The patient complained of a sharp, lancinating pain shooting through the mass, and also of great difficulty in swallowing solid food. A friend who accompanied her to the hospital stated that the tumor was growing rapidly, and had doubled in size within a few weeks.

The rapidity of the growth of the tumor, and the certainty of its soon breaking down in ulceration, by which the pharynx and soft palate would become involved, and thus cause death from starvation through inability to swallow, and also there being no glandular involvement, decided me to operate, notwithstanding the advanced age of the patient.

The case being laid before the patient, an intelligent woman, she declared that she preferred the risk of an operation to the certainty of a tedious death, and the further continuance of the sharp and almost constant pain from which she was suffering.

In consequence of her feebleness and extreme age, the operation which promised the least loss of blood, the galvano-cautery, was selected. Under other circumstances, viz., a younger and stronger patient, my preference would have been for the knife.

The galvano-cautery loop was made to encircle the tumor, which was then seized with a double hook and drawn as far as possible from between the pillars of the palate, the loop then pushed outward between the pillars, tightened, and the mass was removed without difficulty. A broad stub was then substituted for the loop, and the entire surface between the pillars thoroughly cauterized; no blood was lost.

Daily applications of a spray of the peroxide of hydrogen were made, and a wash of carbolic acid used every two hours. In ten days healing had taken place and the patient was discharged, but still kept under observation. After ten weeks the parts have a healthy look, there is no pain whatever, and she appears stronger and better in every way than before the operation, and will probably live several years.

The following is the report of Dr. Charles Heitzman,

to whom the tumor was given for microscopical examination:

"The tonsil, after having been hardened in a dilute chromic acid solution, under the microscope exhibited the following features: The follicles and interfollicular cords are densely crowded with lymph-corpuscles of varying sizes, but everywhere non-nucleated. Between groups of such corpuscles a small amount of a myxomatous (stellate) reticulum is seen, arranged without any regularity. The capsules of the follicles, toward the periphery, show scanty fibres of connective tissue, in the meshes of which numerous granular, non-nucleated protoplasmic bodies are imbedded. The epithelial cover is much thinned.

Diagnosis: Lympho-sarcoma of a pronouncedly malignant type. "Yours truly,

Signed, C. HEITZMAN."

The above case is of more than ordinary interest, not only because of the advanced age of the patient, being the oldest of which I can find record, but also from the rapid healing of the parts after the operation and the non-recurrence of the growth.

65 WEST THIRTY-EIGHTH STREET.

THE LOCAL ACTION OF SALICYLIC ACID IN THE FORM OF A LINIMENT.

BY THOMAS H. MANLEY, M.D.,

NEW YORK.

IN a recent issue of *Le Journal de Suisse-Romande*, Dr. Bouget Lausanne presents a contribution, on the great value of salicylic acid, when applied externally, in the form of a liniment, in either acutely or chronically inflamed rheumatic joints.

He recommends that the salt be rubbed up in sweet-oil, and then applied. By observations and experiments which he had made, he was able to prove that it was promptly absorbed by the integuments, and appeared in the urine within two hours after its external application. He showed that the integument had great capacity for the rapid absorption of this drug, and he moreover demonstrated, that when so administered it might be utilized in the very young, or those suffering from cardiac complications, when its action in subduing internal inflammation was even more decisive than when taken by the mouth.

It struck me as one of the most valuable additions to the Pharmacopœia, if it were all that this author promised for it, and I decided to put its merits to the test in the near future.

It may be said now, that from the number of cases which I have had an opportunity to employ it on, that it has by far exceeded my expectations.

Its action is marvellous in muscular rheumatism; in painful joints, whether they are inflamed or not; in lumbago, sciatica, intercostal neuralgia, and muscular pain of any kind. It has served me in gonorrhœal rheumatism equally as well.

The formula of the Swiss surgeon answers in ordinary cases of rheumatism; but the excess of acid settles as a thick deposit in the vial; so that, unless it is made up fresh, as used, it cakes and requires considerable and prolonged agitation, before it is mixed well with the oil; besides, in those cases in which we suspect a neuralgic element, it occurred to me, that it would detract nothing from its virtues to add a little laudanum and chloroform. Therefore I have substituted the following formula, which is always ready, will keep indefinitely, and may be employed in most any of these hyperæsthetic diseases, the most pronounced symptom of which is pain:

℞.	Chloroformis puræ	ʒ v
	Tr. opii,	
	Acidi salicylici	āā ʒ iv.
	Spts. vini rect. cionc.	ʒ iv.
	Olei dulcis, q. s. ad.	ʒ xii.

M. S.: Liniment, use *ad lib.*

In young children the laudanum and chloroform should be omitted. It should be applied warm and be well rubbed in. In certain cases it may be well to moisten a cloth, a piece of flannel preferably, and leave it on over the painful parts.

There can be no question in my mind that the modern exacting studies of microscopical anatomy and bacteriology, combined with the abnormal frequency of surgical operations, have weaned the student off from that domain of the healing art, more useful than all the others put together, viz., therapeutics. There has been altogether too much cutting done during the past decade, and materia medica has been practically thrust out the back door.

During the month of November of this year (1893), three cases of supposed appendicitis have been sent into my service at the Harlem Hospital for laparotomy and appendisectomy. All went home on their own legs, within two weeks after entrance.

Three cases of arthritis have come under my care for arthrotomy and scraping of their joints, within the past year, which all recovered without any recourse to the knife. A lawyer sent for me to see him, in a private hospital apartment; on the next day the metacarpo-pharyngeal articulation of his great toe was to be opened and scraped. I ventured to inquire of the house physician whether or not the patient had been well dosed with colchicum; for if he had not, the operation might put him or his patient in a "scrape." For a day or two following he was freely purged, and in a week he walked out of the hospital with the joints all whole.

No doubt a return to our "old love" will make operating material scarce; but, when it is constantly borne in mind that all surgical operations are the opprobia of the healing art, and that nothing justifies them except the imminent danger of an organ, or life itself, and then only when all other palliative measures have failed they will be performed less frequently.

A SUCCESSFUL CASE OF CÆSAREAN SECTION.

BY PHILANDER A. HARRIS, M.D.,

PATERSON, N. J.,

VISITING PHYSICIAN TO THE PATERSON GENERAL HOSPITAL.

A. M——, primipara, aged eighteen, born in the United States, a rather diminutive person with slight suggestion of rachitis, but apparently healthy and fairly well nourished, four feet six and one-half inches in height, with the following pelvic measurements: distance between iliac crests, 22 ctm.; anterior superior spinous process, 21½ ctm.; external conjugate, 16½ ctm. From promontory of sacrum to symphysis pubis, 7 ctm.; while the other internal diameters were all greatly shortened. She was believed to have passed slightly beyond the ordinary period of utero-gestation. The uterus was thought to contain a large child.

On April 9, 1893, very slight labor-pains began at two o'clock in the morning and continued for eighteen hours, or until ether was administered, at which time the os was dilated to a degree admitting only the index-finger.

The patient having been prepared in the manner usual in cœliotomy cases, was anæsthetized and removed to the operating-room at a quarter to nine in the evening. Incision was made in the median line of the abdominal wall to a point about three inches above the umbilicus. The uterus was lifted out of the incision, enveloped in aseptic towels, and held by an assistant, while the upper portion of incision in the abdominal wall was closed with silkworm-gut sutures. An elastic ligature was next placed around the lower segment of the uterus and secured. The incision was then made in the anterior median line of the uterus. Scissors were employed to enlarge this incision, and it was interesting to observe the pouching and semi transparent membranes protruding from the opened uterus. When the incision was deemed sufficiently large, an as-

sistant introduced a finger in the upper angle of the incision to limit in a degree the contraction of the uterus.

The membranes were ruptured, after which a living male child (weighing eight and one half pounds) and the placenta and membrane were quickly removed. The cavity of the uterus was carefully irrigated with a one to forty solution of carbolic acid, the irrigating fluid escaping through the slightly dilated os and the vagina. The incision in the walls of the uterus was closely sutured with strong silk. The number of sutures employed was probably fifteen or sixteen.

When the uterus was released from the elastic ligature very slight hemorrhage appeared at one point of the uterine incision, which was readily controlled by the introduction of another suture. The uterus being now firmly contracted and the hemorrhage controlled, the peritoneum was brought together with running catgut suture.

The abdominal wall was closed with silkworm-gut, but it was so thin that a surprisingly large number of sutures were required to effect satisfactory coaptation.

Very little blood was lost during or following the operation. I should think very much less than we are accustomed to in an ordinary case of labor. Twenty-nine minutes elapsed from the beginning of operation to the delivery of child and placenta, while sixty-six minutes more were required for the completion of the operation. The patient rallied rapidly from the operation.

The further treatment of the case was not unlike that usual in cœliotomy cases. The temperature was taken every four hours for one week, the highest point observed was 101⅘° F., while the average temperature, reckoned from all observations, was 99⅖° F.

On the sixth day after operation a rather free flow of milk occurred. The child was put to the breast, and afterward regularly nursed and mainly nourished at the maternal fount.

The mother made an excellent recovery, the child grew rapidly, and both were discharged from the hospital, in a condition of health, June 12th following.

26 Church Street.

A CASE OF QUININE POISONING.

By ISHAM G. HARRIS, M.D.,

HUDSON RIVER STATE HOSPITAL, POUGHKEEPSIE, N. Y.

X. L——, aged twenty-six, widow, American; occupation, nurse; habits and previous health, good. No hereditary history of neuroses or idiosyncrasies, so far as can be learned.

January 15, 1892, patient complained of the following symptoms: slight headache, nausea, and a feeling of tiredness, with spots before the eyes, and inclined to constipation; bad taste in the mouth and the tongue slightly coated. Appetite and digestive functions fairly good. Patient had also experienced slight chilly sensations up and down the back. At 4 P.M., was given two grains quinine in pill form. In about twenty minutes after taking, patient began to feel a slight tingling or prickling sensation in the ends of the fingers and toes which gradually extended up the extremities. A few minutes later this feeling extended over the whole body, and there was sneezing, profuse lachrymation, coryza, roaring in the head, itching of the body, congestion of the conjunctivæ, face swollen and flushed, and also swelling of the tongue and lips. About three hours after taking the quinine there appeared over the body, from head to foot, a very intense red rash, scarlatinal in appearance, with an aggravation of all other symptoms—the itching being almost unbearable. The rash did not appear to be elevated at any place except on the back and shoulders, and at those places it exhibited a measley form, the elevations being as large as a pin-head. Temperature was not measured, but it was apparently elevated. The heart's action was at first stimulated and later depressed. Respiratory movements slightly increased and the patient was very restless. About 10 P.M. patient began to have a menstrual flow (nine days since catamenial period, and catamenia have been regular), but this stopped during the night. At 10.30 the acute symptoms began to abate. At 2 A.M. (the same night) patient was more comfortable, the rash disappearing, but there was severe headache, some hebetude, and an "indescribable, peculiar feeling" in the lungs with a good deal of restlessness. Given bromide potash, grains twenty, and chloral hydrate, grains ten. This did not give any rest, and the prescription was repeated. When the symptoms were most pronounced, free diuresis was produced and stimulants given.

January 16th.—At 8 A.M., all symptoms of quinine poisoning had disappeared except a slight roaring in the head. In the afternoon patient was up and feeling fairly well. Toward evening, however, began to menstruate again, and on the morning of the 17th she had lost so great an amount of blood that she fainted on two different occasions while attempting to raise herself. As soon as this condition was known patient was given fluid extract ergot, one drachm, with directions to give one-half drachm every four hours until all hemorrhage was fully controlled. Quiet and rest in bed were enforced. There was acute pain in abdomen with all this trouble. Patient remained in bed all of the 18th and 19th. On the 20th she was up, notwithstanding a slight menstrual flow. No further untoward symptoms developed.

Patient states that she has suffered from quinine poisoning on other occasions, once from two grains of the bisulphate and once from a five-grain dose of the sulphate. It appears that the two-grain dose of the bisulphate produced symptoms almost as severe as those above mentioned.

For a history of the attack caused by the five-grain dose I am indebted to Dr. W. L. Burrage, of Boston, and by his kind permission I subjoin the notes made in her case at that time.

"February 17, 1889.—Patient about her duties, but complained of being somewhat tired; with the exception of headache is in perfect health. No indiscretion of diet. At 8 P.M., took a five grain capsule of quinine for headache. On previous occasions had taken repeated small doses of this drug (four grains at a time) for malaria, and had suffered from singing in the ears, not marked, and from tingling sensations in the hands and feet. In half an hour after taking the five-grain capsule patient began to have swelling of the tongue, lips, and face, and tingling of the hands and arms. Symptoms increased in severity, and at 11 P.M. she was very restless and complained of a burning sensation all over the body. Was given a small dose of aromatic spirits of ammonia and antipyrine, and a little later five grains of chloral and thirty grains bromide of potash. Unable to sleep. I was called to see her at 1.30 A.M. She was then tossing about in bed, pupils widely dilated, tongue thick, lips swollen, eyelids and conjunctivæ swollen and injected. There was a diffuse, bright scarlet, punctate eruption, covering the entire surface of the body, face, neck, and limbs. She complained of burning, prickling, and itching. In a few minutes she was seized with a violent pain in the abdomen and vomited freely at about 1.45 A.M., with much relief. When seen a few moments later, the eruption had entirely disappeared. According to the account of the nurse in attendance the eruption reappeared in about fifteen minutes. Was given chloral, fifteen grains, and body and limbs rubbed with zinc oxide one-half ounce, acid carbolic, two drachms, liq. calcis one pint. Itching and scratching, before uncontrollable, now stopped. Began to have a menstrual flow (ceased menstruation a week ago, catamenia always regular). Soon fell asleep and slept until morning.

"To day, February 18th, feels well in every way, no vestige of eruption; a few excoriations on the shoulders and arms.

"February 19th.—On duty to-day. Has ceased menstruating, feels well, except that her joints are sore."

THE TREATMENT OF LOBAR PNEUMONIA WITHOUT OPIUM OR DIGITALIS.

By E. E. REICHARD, M.D.,

POUGHKEEPSIE, N. Y.

The common method of treating pneumonia by the employment of opium in some form in liberal doses, with the free use of antipyretics, has fallen somewhat in disrepute with many practitioners, although there is no doubt as to its superiority to depletion by phlebotomy and other means used by our fathers in the profession, statistics showing a much lower death-rate to-day than under that treatment; still the death-rate is high, and almost every physician can call to mind instances of seemingly simple cases of pneumonia that have resulted fatally from heart-failure or some other suddenly appearing complication. This has caused the profession to make research for some more satisfactory mode of treatment, and has led some to the opposite extreme to that of blood-letting, namely, the employment of heart-tonics and stimulants to the exclusion of all other remedial measures.

The latter method has proved a success according to the reports of some, and a decided failure with others. My experience with the digitalis treatment has been somewhat unsatisfactory, and I think we have a resource in a drug far superior to it, and one that has been used to some extent for many years, viz., ammonium carbonate. That, with the use of aconite in sthenic cases during the first stage, and antipyretics when absolutely needed, employing alcoholic stimulants in asthenic cases after the crisis, or before if demanded, has been with me a very satisfactory line of treatment in cases that looked almost hopeless. In the first stage of pneumonia we find one or more lobes of lung affected in a state of congestion, the capillaries filled, exudation of fibrous elements of the blood in the air-vesicles taking place, pulse rapid, and arterial tension high, temperature increasing, and a general nervous excitability following the initiatory chill.

Now while opium will quiet the patient and relieve the pain, if pain be present, it will also arrest all secretions except that of the skin, raise the arterial tension, and after a brief period of stimulation act as a respiratory depressant, and further mask many of the symptoms, so that the physician does not readily see the real condition of the patient, or the advancement of the disease.

Digitalis, if given at this stage, will increase the force of the heart's action (which at this stage is contra-indicated), raise the arterial tension, act as an excito-motor to the nervous system, and cause gastric disturbance; while it is true it will lower the temperature, if given in large doses, it does so by lessening the blood supply to the tissues, producing headache and an irregularity of the heart's action.

Ammonium carbonate given during the first stage will lower the arterial tension, increase the breathing capacity, thereby assisting to properly oxygenate the blood; prevent coagulation of the fibrous elements of the blood, thus antagonizing hepatization; act as a stimulating expectorant, relieving the air-vesicles of the exudated material, and when given in connection with small doses of aconite, counteract the depressing effect of that drug on the heart.

In treating a case of acute lobar pneumonia seen during the first stage, get a free action of the bowels by calomel or salines, the former being preferable except in sthenic patients; apply either the hot-pack, poultice of flax seed meal, or cotton-batting jacket covered with oiled silk to the chest, and give ammonium carbonate in five-grain doses every two hours, also tincture of aconite one-fourth milligramme every half hour, discontinuing the aconite when free diaphoresis occurs, and its effect is seen on the pulse. Should the temperature exceed 103° F., give acetanalid in doses sufficient to keep it below that, or

℞. Antikamnia,
Quinine sulphate..... .....āā ʒj.

M.: Divide in twenty capsules. Give one capsule every four hours.

This will reduce the temperature, relieve the pain, and quiet the nervous excitability. Many cases treated in this way from initiatory chill will not go on to hepatization.

After the crisis continue the ammonium carbonate, in connection with small doses of ipecac to promote expectoration, and give quinine sulphate in tonic doses, with alcoholic stimulants in asthenic patients, and whenever the condition of the patient demands.

This treatment, if faithfully carried out, with nutriment given in the form of milk every three hours, and the patient allowed to take plenty of pure water to promote free action of the kidneys, under favorable sanitary surroundings will, I am confident, result in as low a rate of mortality as any method of treatment known to the profession to-day.

THE TREATMENT OF INFLUENZA.

By WILLIAM HENRY THAYER, M.D.,

BERKSHIRE, MASS.

As I am out of town, out of practice, and no longer see the MEDICAL RECORD, I do not know whether the treatment of influenza which some of us in Brooklyn employed with marked success in the epidemics of 1891 and 1892 has been adopted at all generally. It was treated as we should treat diphtheria, with bichloride of mercury, adopted on the ground of its being a powerful germicide. I treated all my cases in that way, and with excellent results. In severe attacks it was given in doses of one-thirtieth of a grain every half-hour, at the outset, for several hours, and continued at longer intervals afterward. The effect was always good on the prime disease and the convalescence, usually so tedious, and in lessening the frequency of secondary affections.

If this treatment is not already used generally, I wish you would call attention to it in the MEDICAL RECORD.

A SPLINT FOR THE TREATMENT OF ORDINARY FRACTURE OF THE LEG OR ANKLE.

By WILLIAM MEACHER, M.D.,

PORTAGE, WIS.

I WISH to call attention to this splint, as being very simple and efficacious, and particularly adapted to the treatment of ordinary fracture of the leg and ankle. Of course, a fracture near the knee requires a splint which extends more or less on to the thigh.

A fracture of the leg or ankle is easily dressed with this splint, and when applied it has all the advantages of a plaster-of-Paris cast without its disadvantages. When applied, the patient is not compelled to lie on his back, but may lie on either side, and may get about on crutches quite as soon as with a plaster cast, the limb being quite as secure in this splint as in a cast. It is light, being made of perforated sheet zinc, the same material of which the Levis splints are made.

A very important part of this splint is the foot piece (made the same as the foot piece of the Levis double inclined plane). It holds the foot perfectly, so that the fracture is not disturbed by any crank-like motion of the foot and lower fragment. It also protects the toes from the contact and weight of the bed clothing. Another very important feature is, that the splint encircles, or comes around, the limb sufficiently to hold it perfectly secure when bandaged. With this splint it is very easy to examine the fracture at any time, simply by removing the bandage, the patient lying on his back for the time, and the limb lying in the splint. If you wish to examine the side of the limb, the side of the splint may easily be bent or sprung out and away from the limb sufficiently to examine it fully, without disturbing the fracture.

If it is desirable to make pressure on any part of the limb, make a compress of cotton or flannel, and if the pressure is required at the side, put the compress in be-

tween the limb and the splint; if on the anterior portion, lay the compress on where it is required. then by extra turns of bandage over the compress make as much or as little pressure as you choose. A flannel bandage should be used.

In applying it to a compound fracture, an opening for the escape of discharges may readily be made if necessary in any part of the splint with a pair of strong shears.

The advantages claimed for this splint, namely, the foot piece, the covering of so much of the limb, the flexibility, making it so easy to examine the fracture, its lightness and strength when bandaged to the limb, the facility with which it is applied, etc., will, I believe, be appreciated by anyone who uses the splint. I speak from my own experience, having used it for more than fifteen years.

It is made and sold by Charles Truax Green & Co., of Chicago; price, $2.50.

THE TREATMENT OF CHOLERA.

By H. ROSAHNSKY, M.D.,

NEW YORK.

THE following preparation has been used by me with great success in the beginning of cholera where there is profuse vomiting and diarrhœa. The same preparation has been highly recommended by Professor Botkin, of Russia, and it is very extensively used by the Russian physicians. This preparation goes under the name of Guttæ Botkina.

℞. Tr. chinæ comp.,
Anodyn. Hoffmani.....āā 15.0
Acid mur. dil..... 2.5
Ol. menthæ pip..... 0.3
Chinini muriatici..... 2.0

M. Sig.: Twenty drops three or four times a day during cholera.

In cholera infantum I use this preparation in divided doses and a larger proportion, according to the age, or in the following manner, which gives excellent results.

℞. Acid mur. dil..... 2.0
Liquor anod. Hoffmani..... 6.0
Bismuth salicyl..... 6.0
Acid carbol. (C. P.)..... 0.12
Glycerin..... 12.0
Aqu. menthæ pip.....ad 60.0

M. Sig.: A teaspoonful every hour, according to age.

For choleraic diarrhœa, the following preparation is also good:

℞. Tr. opii..... 4.0
Essentiæ menthæ,
Liquor anod. Hoffmani.....āā 8.0

M. Sig.: Twenty drops four or five times a day.

The Canarsie Board of Health.—Dr. William S. Tromer, health officer of Canarsie, writes us in terms of severe arraignment of the Board of Health of that place. He calls attention to the fact that outside of the cities of New York, Brooklyn, Buffalo, Albany, and Yonkers, all the towns in the State have health boards composed of the supervisor, town clerk, four justices of the peace, and a citizen member. He very rightly declares that while these gentlemen may be eminent in their respective callings, they have no special fitness as guardians of the public health. In fact, holding elective offices, they are willing to grant licenses for all sorts of public nuisances, lest their opposition to the latter might interfere with their political prospects. Dr. Tromer points out several flagrant abuses of this kind which have been allowed to continue in Canarsie. His remedy is legislation which shall transfer the power now entrusted to the local health boards of towns to the State Board, with health officers as State officials, whose expenses are to be paid out of the State treasury, and not from the town. He proposes that the whole State should be districted, and the officer of each section made responsible for its public hygiene.

Progress of Medical Science.

Non-parasitic Liver Cysts.—Dr. W. Müller has observed a liver cyst so large as to give clinical symptoms, and which was very probably in genetic relation with the gall duct system. The author has operated upon such a cyst, which filled almost the entire abdominal and pelvic cavities, and simulated an ovarian tumor. The patient, a cachectic woman, aged fifty-nine, had observed the tumor for some ten years. Only during the last year had she suffered serious annoyance from the growth, though for five years it had been a source of discomfort. She complained of frequent micturition, sometimes with retention, pain in the back, abdominal cramps, and attacks of weakness. Finally, she became very weak, from, what was later discovered, hemorrhage into the cyst. At the operation it was discovered for the first time that the tumor had its origin in the liver. A thick pedicle attached the tumor to the lower and front surface of the organ. Otherwise the surface of the liver presented a normal appearance. On account of the very weak condition of the patient, a radical operation was not undertaken. The cyst was widely incised and six litres of chocolate colored fluid, with much fluid and coagulated blood of various ages, was liberated. From two-thirds to three-fourths of this was evacuated. The remaining tumor was fixed with the pedicle into the abdominal wound. The bleeding was very profuse, and controlled by the cautery and iodoform gauze. The patient recovered. The wound was healed in four months. The part of the cyst lying outside of the wound was partially uncovered; the rest was cut away. One and one half year later the patient was well and without recurrence. Müller is of the opinion that this case, as has been repeatedly observed in animal and human pathology, is one of cystadenoma of the gall-ducts—a benign tumor.—*Annals of Surgery.*

Injudicious Nasal Operations.—In opening the discussion on this subject at the late Pan-American Congress, Dr. Hobbs, among other things, said: "If our friends, the gynecologists, have their nymphomaniacs, I think we too may have our rhinomaniacs. We have a class (and it is a rapidly increasing class) of patients who consult us with the avowed purpose, to use their own language, 'of having their noses burned out.' In some respects these two classes are analogous, in that the neurotic factor is often present also in our rhinomaniacs, as it is always present in nymphomaniacs. My point is that we may, without much exaggeration, lay the blame of the injudicious, or at least the unnecessary, operation, when we make it under such circumstances, upon the patient himself, unless we place it upon a higher plane, and refuse in all such cases even the pretence of an operation, as a placebo, or for its moral effect, when its necessity is not indicated. While judicious and properly executed rhinal operations have done, and are doing, an immense amount of good, for this very reason the temptation is increased in many instances to do operations that were better not to have been done, particularly by the younger men just making their *entrée* into this special line of work. They are loath to allow an opportunity to pass to saw a septum, to drill an exostosis, or to cauterize a turbinate. The mere suggestion of a septum spur, or a bony protuberance, or an enlarged turbinate, is too often deemed a sufficient reason for a surgical procedure, even though no subjective or objective symptoms may exist. When we are reminded of the large area of nasal mucous membrane, its functions should at once be suggested. The nasal space was intended to breathe through, and only secondarily to serve as an olfactory organ. As this great expansion of mucous surface, twice that of the so-called throat, is intended to perform the important functions of moistening and warming the inspired air, the necessity of its preservation should never be lost sight of. Hence any nasal operation made without reference to the

mucous membrane preservation is not only injudicious but harmful, provided the nature of the case does not necessitate its destruction. And again, where no operation can be made without resulting in a large cicatrix, the question may arise, would it not be better left undone? In cases where chromic acid or any other escharotic would seem to be more appropriate on account of the timidity of the patient, or for any other reason, the toxic sequence should always be considered, otherwise the operation may prove to have been an injudicious one. Septum deflections, spurs, and exostoses should always be carefully measured before any operative procedure is resorted to, else a perforation may result that would be worse than the primary condition. The drill is, in my opinion, almost always an injudicious device, for the reason that it necessarily destroys so much mucous membrane and leaves a rough cicatricial surface, although I find myself resorting to it in some cases of prominent exostoses."—*Atlanta Medical and Surgical Journal.*

Physiological and Pathological Proportions of Urea.—For some years Dr. Kache has been making observations as to the varying proportions of the total amount of urea excreted daily to the total amount of urine passed, hoping thereby to obtain relative curves which might prove to be of importance in the diagnosis and prognosis in certain diseases, especially in the specific fevers and those of malarial type. His conclusions may be summarized as follows (*The Lancet*): Apart from the well-known increase of urea in febrile conditions generally, it is impossible to formulate any particular proportion in which this increase occurs. The variations which occur do not seem to possess any practical value in the treatment of the affection. On the other hand, a comparison between the amount of urea found in the urine and the actual quantity of urine passed, presents many points of interest. If these quantities are expressed graphically in curves, in the physiological state, there is a close parallelism between the two curves, while in febrile conditions, of whatever type, the urine curve during the period of fever is always lower than that of the urea, while at the period of crisis and during convalescence the curves are very different. In patients suffering from fever of a non-infectious type the urine curve is inferior to the urea during the febrile period, mounts up as the temperature falls, and gradually assumes the physiological condition. In patients suffering from yellow fever the urine curve remains constantly below that of the urea, and even several days after all fever has subsided. In those forms of febrile attacks so frequently met with in the tropics, characterized by suddenness of onset, acute gastric symptoms, profuse sweats, and usually rapid recovery, the urine curve is lower than the urea while the temperature is high, rises above it for two or three days after defervescence has occurred, and then continues to rise for another four or five days, departing more and more from the normal course; thus exhibiting in all such cases a very considerable difference between the two curves, partly on account of the relatively large quantity of urine passed, and partly on account of the relatively small amount of urea secreted. From these facts it will be seen that there is a marked difference between this type of fever, which Dr. Kache terms "telluric," and yellow fever in regard to the relative proportions of urine and urea; which confirms the opinion generally held that yellow fever should not be regarded as of malarial origin.

The Fever of Phthisis in Relation to Prognosis.—Dr. Strümpell emphasizes the importance of recognizing the particular type of fever present in cases of pulmonary tuberculosis. He says that if one is to arrive at a correct appreciation of any particular case, special attention must be paid to the question of prognosis, a question in which the physical condition of the lungs plays but a subordinate part. On this point there are other far more important factors to be considered, such as hereditary taint, the general and constitutional necessities of the patient, among the latter of which Professor Strümpell considers chronic alcoholism to be the most unfavorable; the pace at which the disease has hitherto progressed; and finally the fever. As to the cause of the fever, Strümpell is of opinion that, except in miliary cases, it is not to be ascribed to the tuberculosis, but to secondary inflammatory processes, set up by the invasion of pus and other cocci. In a number of cases there is, as everyone knows, no fever at all. The patients feel well, their lung trouble being stationary or making but minimal advances. Should, however, fever set in, its type is of the greatest importance for establishing a prognosis. Strümpel classifies the various forms of fever in phthisis as follows: 1. *Status subfebrilis;* here the morning temperature is normal, the evening, 100.4° to 101.3° F. In such cases the disease makes but slow progress, and amelioration may be expected by improving the general condition of the patient. 2. *Febris hectica intermittens.* With this type of fever (morning nearly normal, evening, 101.3° to 104° F.) the disease is steadily advancing, though in such cases a feeling of good health may be maintained for a considerable time. 3. *Febris remittens* (morning, 100 4° to 101.3° F., evening, 103.1° F.). This type is far more unfavorable, as it points to the presence of lobular inflammation. 4. *Febris continua.* Except in miliary tuberculosis, this form of fever is found almost exclusively in cases of phthisis which start with acute symptoms, though it may be found interpolated for several days in cases in which the fever otherwise runs a remittent or irregular course. In either case the prognosis is unfavorable. The last remark is equally true of Strümpell's fifth fever type, that totally irregular form which is observed throughout the whole illness in many cases, though only in the last stage in others. That exceptions to the above rules will be found goes without saying, but it is none the less a significant fact, that in nearly all cases of phthisis in which pyrexia is present, the fever invariably assumes the form of one, and only one, of the types in question. Any change which may take place is brought about by the presence of complications, and it is frequently observed that the fever, set up by intercurrent diseases, lasts on after they have subsided, thereby showing that they have instilled renewed vigor into the phthisical process. Granted that the fever forms a most important indication in prognosis, it follows that it must also be the standard by which antiphthisica must be tested, for it is only by their effect on the fever that a just estimate of their value can be arrived at. On these grounds Strümpell rejected both tuberculin and creosote in the treatment of phthisis; the former he considers to be absolutely injurious, having frequently seen apyretic converted into febrile forms by injections of Koch's specific.—*Muenchener medizinische Wochenschrift.*

Anæmias of Tuberculosis and Carcinosis.—At the Berlin Medical Society Dr. Growitz recently brought forward this subject. He said that the anæmias of both diseases differed very considerably, not only as regarded the two diseases, but in different cases of the same disease. In examining the blood specially, he had taken from one and a half to two grains of blood by puncture with a hollow needle from a superficial vein in the forearm (*Medical Press*). Drawn in this way there was no admixture of lymph. The determination of the dry residue was made in vacuo over sulphuric acid. The medium average value found in patients whose blood condition was not far from the normal, was 21.5 per cent., for the serum 10.7 per cent. He had performed exact analysis in thirty-two cases of tuberculosis, which, as regarded degree of severity of the disease, might be divided into three groups. In the first might be included those cases that were in the first stage of the disease, had slight dulness in the apex, and slight expectoration, with paleness. These cases showed marked anæmia with diminution of red corpuscles, of dried residue, and of blood-serum. The second group comprised cases in which the lung disease had already made considerable progress. These

patients had cavities, were a good deal emaciated, had no particular fever, and were free from complications. This large group showed considerable differences from the last, the red blood corpuscles were normal in quantity, the specific gravity was also normal. The condition appeared paradoxical as the cases were advanced in cachexy. The third group comprised those cases which had been attacked with hectic fever in consequence of secondary infection from the cavities. Here there was a diminution of all the values of the blood, which steadily gets worse with the advance of the disease. The anæmia in cases of acute secondary processes in the lung was very remarkable. In laryngeal tuberculosis, however, associated with stenosis, there was thickening of the blood. As regarded the thickening of the blood in the second group of cases, it was certainly not due to sweating. He would, however, refer to the observations of Gärtner and Römer, of Vienna, who found that tuberculine had a lymph driving action, causing a surplus of blood in the vessels, and in consequence a thickening of the blood. He had sought to ascertain whether the tuberculous products of the lungs had a similar action. On experimenting with a rabbit he found that the specific gravity of the blood, which before the injection of the tuberculous products was 1.040, rose in thirty minutes to 1.049. The dry residue rose from 17.06 to 18.8 per cent. He thought his observations served to explain the paradox of the second group of cases. As regarded the condition in carcinoma they were much more simple. His observations, made on thirteen cases of cancer, agreed with those of other observers. In carcinomatous cases with cachexia all the values of the blood were diminished, and it was only under certain circumstances, in which this body was poor in water, that the blood was thickened. He thought the condition was explained by a separation of certain toxic substances from the cancerous growth which exerted a destructive influence on the protoplasma, and thereby causing an impoverishment of the blood of its solid constituents. He had prepared an extract from a fresh piece of carcinoma that, in the course of several experiments, always had the effect mentioned of impoverishing the protoplasm of the blood.

Simplicity in the Treatment of Nasal Obstructions.—Dr. Spitzer advocates simple measures in the treatment of nasal obstructions. In cases of hypertrophic rhinitis he prefers weak reagents, such as iodine and iodide of potassium, to the ordinary astringents. In severe cases associated with induration he recommends chromic and trichloracetic acid preceded by the application of cocaine. In this method only small tracts should be taken in hand at each sitting. The galvanic cautery is also applicable with the same precautions. After such treatment he closes the orifice with a cotton wool plug, which is retained for twenty-four hours, and otherwise enjoins rest of the nose. Among foreign bodies he mentions the occurrence of large quantities of fly larvæ which must be removed with a hook. Adenoids he separates from their attachments by means of Gottstein's circular knife, and he considers the removal with the finger insufficient. He condemns the modern anxiety to operate on the nose with saws, chisels, etc., which should be resorted to only when absolute necessity exists, owing to the frequently occurring sinus, thromboses, and meningitis. He also points out the inadvisability of general anæsthesia in such cases, and the insufficiency of the local effects of cocaine. All major operations are to be avoided when simpler means suffice.—*Centralblatt für Therapie.*

Rest in Chlorosis and Heart Disease.—Two papers on the utility of rest, one by Dr. Frederick Taylor on its use in chlorotic anæmia, the other by Dr. Lauder Brunton on its importance in cases of cardiac failure, have recently been published. Dr. Taylor draws attention to the rapidity with which improvement shows itself in cases taken into hospital, where almost as a matter of routine they are put to bed and kept there, compared with the tedious progress of cases among out patients, who endeavor all the time to carry on their work, or even among private patients who may have every advantage of food and fresh air, but who, by the very exercise they are encouraged to take, expend more than they gain, and thus fail to recover. Where income is not equal to expenditure, no doubt the pleasantest way of making them balance is by increasing the income; unfortunately it too often happens that the only possible way is by diminishing the expenditure, and in many cases of chlorotic anæmia, in which the varied forms of iron and aperients have failed to give relief, it will be found that the addition of complete rest in bed for a few weeks will make the difference, initiating an improved nutrition which can then be maintained by ordinary treatment, besides saving the heart from that risk of dilatation to which effort during anæmia always exposes it. In Dr. Brunton's remarks there is a great deal which is worthy of most careful consideration by those who have to arrange the daily life of cardiac cases. The first point is that rest is not required because of cardiac disease, but because of cardiac failure. A typical instance is given of a healthy-looking man, accustomed to hunting and fresh air, in whom a rasping *bruit* was discovered. "What," said the doctor, "would you do if I were to cut off your hunting?" "I should shut myself up in a billiard room and drink whiskey and water, and then I should get ill," was the response. In cutting off a man's exercise one always ought to consider what is the alternative, and to bear in mind how important is the muscular work for the maintenance of health. To deprive a man of exercise may, in fact, only initiate a series of degenerative changes which may make the work of the heart far heavier than before; whenever, then, it becomes necessary to order any serious limitation of muscular work a careful dietetic *régime* should be laid down at the same time to prevent the occurrence of such evil consequences, and, so far as they can be obtained, passive substitutes for exercise, such as massage, should be ordered. The second point to which attention is drawn is, that when in cases of cardiac failure it becomes necessary to order rest, care should be taken that it is obtained in such degree as not merely to take off the edge of the patient's discomfort, but to get well over the difficulty, and to restore the proper balance between power and work. When there is dropsy and orthopnœa, with rapid breathing, it is not always recognized that the very utmost rest the patient can obtain is still a state of labor; muscles are at work to maintain the body in its position, muscles are hard at work to keep up the head, and respiration is only performed with trouble and constant effort. These things are essential and must go on, but as regards all else the patient must lie absolutely torpid and allow everything to be done for him if he is to obtain the true benefit of rest; no journeyings to the water-closet, no efforts to pull pillows about, no attempts to feed himself must be allowed; absolute passiveness must be the rule; and Dr. Brunton points out that many patients who, under an imperfect kind of rest, have been steadily failing, may by rest absolute, by feeding with a diuretic substance such as milk, and by careful massage, be brought back to a state of comfort and comparative health from a condition in which death seemed only a few days off.—*The British Medical Journal.*

The Influence of Surgery on Modern Obstetrics.—Dr. Opie, of Baltimore, says that from the earliest times there has always been a close relation between midwifery and surgery. The department of midwifery was entirely in the hands of women, and it was only when the lying-in woman was in a desperate condition that male assistance, generally of a more or less directly surgical nature, was called in. The invention of the midwifery forceps in the seventeenth century marked an epoch in the history of obstetrics, and at the same time enormously increased the number of cases in which the use of instruments—that is to say, assistance of a surgical nature—was indicated. The field of obstetric surgery has similarly been widened

in our own time by the success of the modern Cæsarean section and of modern symphyseotomy, a success largely due to strict adherence to antiseptic principles. Dr. Opie recognizes three periods in tracing the relation between obstetrics and surgery. The first was the destructive epoch, when craniotomy was the chief operation for which instrumental assistance was employed; the second was the reactionary period, when the pendulum swung too far in the other direction and obstetric surgery was almost obsolete; and the third period was marked by the introduction of the forceps. We may, perhaps, be allowed to add a fourth period, which may be called "the antiseptic period," being characterized not only by the greatly increased success of the old operations when performed in accordance with antiseptic principles, but also by the increased safety with which a woman may pass through a normal labor if those principles are faithfully and intelligently adhered to (*The Lancet*). Just as the surgeon has to consider and provide for the absolute cleanliness of himself, his patient, his instruments, and his assistants, so in a case of labor, as Dr. Opie very rightly insists, it ought to be the first practical consideration to secure the absolute cleanliness of all those concerned in the case, as well as of all instruments and appliances. The need for asepsis concerns the monthly nurse nearly, if not quite, as much as the obstetrician. We observe one reason here given for the fact that so many nurses fail in their appreciation of the importance of antisepsis which is often lost sight of. It is that it often happens that a particular nurse works with many practitioners whose methods may vary widely. Some—we trust a vanishing minority—ignore the use of antiseptics altogether; some, again, use one antiseptic, others, another; some use antiseptic douches after delivery, while others do not. It is not to be wondered at that an imperfectly educated woman under these circumstances should at times be led to conclude that the whole business is only so much fuss and worry, and may be safely disregarded in the spirit, if not in the letter. Much of Dr. Opie's paper is taken up with the precautions to be taken and rules to be observed in the application of the forceps, and especially he gives a note of warning against the use of the forceps when the cervix is not fully or at least sufficiently dilated—a fertile source of serious danger both immediately, as well as during the lying in period and afterward. As Dr. Opie says, "It is a great gift in an obstetrician to be able to wait and do nothing. The obstetrician who is inappreciative of nature's power and ingenuity, and will not give her time in labor, has great need for the surgeon and the undertaker."

Psychical Sequela of Gastric Dilatation.—Dr. Devay has instituted a number of observations with regard to the influence of gastric dilatation on the nervous system. He believes that in those predisposed to mental alienation, dilatation may directly cause insanity, and that in the previously insane it is apt to modify the form of mental disease. Just as the septic uterus, after an accouchement, may poison the entire system, and superinduce puerperal insanity, so the dilated stomach may produce a toxic condition with a strong tendency to melancholia. Bayle and Maury have already pointed out the relation existing between gastro-enteric disease and some forms of melancholia, but they interpreted the latter as a sympathetic phenomenon. It rested with Dr. Devay to demonstrate the process to be one of genuine intoxication. He explains the manner in which dilatation of the stomach produces its psychical effects as follows: The activity of the gastric juice being markedly diminished in a dilated stomach, bacterial fermentation is set up, the toxic products of which profoundly affect the central nervous system, calling forth phenomena of either a depressive or convulsive nature. Drs. Bauveret and Devic have shown how changes of character were wrought by dyspeptic troubles, and how in the predisposed the latter may prove the stepping-stone to mental alienation. Individuals afflicted with gastric dilatation present a state of mental depression manifested by premature weakening of all intellectual faculties, as of memory, concentration, will-power, judgment, and of receptivity for moral impressions. The influence exerted by gastric dilatation in the insane is also well illustrated by the modification which the pre-existing form of insanity undergoes when by dilatation of the digestive function the mental disease readily lapses into its previous form. Dr. Devay recommends in all of these cases the institution of an active gastric and intestinal treatment. The asepsis of the alimentary tract should be insured with all means at our command. A free evacuation of the bowels is to be induced regularly. If feasible, the stomach is to be subjected to frequent lavage with a 0.50 per cent. naphthol solution, while internally preparations of naphthol combined with magnesia are to be administered.—*Journal de Médecine et de Chirurgie.*

The Pathological Aspect of Electric Lighting.—The Paris correspondent of the *Lancet* writes that at a recent meeting of the Academy of Medicine, M. Lancereaux exhibited the lungs of a polisher of carbon terminals for the electric arc-light, the said organ being transformed into veritable blocks of carbon, and large vomicæ being also discovered. The deceased was, up to the age of thirty-six years, a vigorous stone-mason. He was then transferred to a workshop eight metres long by seven broad, where, with eight other men, he was engaged in polishing on stone mills charcoal for electric lighting purposes. The shop was so badly ventilated that sometimes the men could not distinguish each other through the charcoal and stone dust filling the atmosphere. The man continued to work thus for six years, each day's work extending to ten or twelve hours. For a year before he ceased work altogether, he had coughed and expectorated black sputa. He was admitted into hospital in the winter of 1890–91 for bronchitis after influenza, and he was then expectorating black sputa in large quantities, in which particles of carbon could easily be distinguished under the microscope and by chemical tests (resistance to strong acids). In 1892, he was re-admitted in an emaciated condition, and bacilli could be detected in the black sputa secreted by the numerous cavities. M. Lancereaux very truly says that every new industry that springs up is worthy of the physician's notice, in that new dangers to health may thus be created. He claims for the modern class of toilers better ventilated workshops. Strange to say, he does not suggest the employment of respirators as well.

Nitrate of Aconitine in Facial Erysipelas.—Dr. Tison has used this remedy since 1888, in every case of facial erysipelas which has come under his treatment. The results have been highly satisfactory. Pain and other symptoms have been rapidly subdued, save in two instances, and in neither of these could the complications which arose be due to the treatment. Although nitrate of aconitine is highly poisonous, if used as suggested by the author, the danger of untoward symptoms is very slight. The alkaloid is dissolved in a mixture of glycerine, alcohol, and distilled water, the mixture having the same specific gravity as water, and containing one milligram in fifty minims. Only two to four milligrams are required in any one case. The method of procedure is as follows: According to the condition of the stomach, either an emetic or a purgative is administered, immediately after which nitrate of aconitine is given in a mixture containing one milligram for the twenty hours' dosage. The affected part is painted with a saturated ethereal solution of camphor, which acts as an excellent sedative. When all signs of inflammation have subsided, the part is washed with a solution of lysol.—*La Semaine Médicale.*

The Cinnamic Acid Treatment of Tuberculosis is said to be even more effective than that by creosote and guiacol.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 3, 1894.

THE INCOME TAX AND MEDICAL MEN.

THERE are a great many physicians, we regret to say, to whom the question of a two per cent. tax on all incomes above $4,000, will not be of much interest. But there is a very considerable number whose yearly earnings reach or exceed this sum. We are safe in saying that in all cities of 10,000 inhabitants or more, there are physicians who earn more than the above minimum; and the proposed direct tax upon their savings, together with the publication of their financial standing, ought to awaken among them very decided emotions.

For there is no doubt that such a tax as is proposed will act with particular severity upon medical men. The reason is that the physician who earns much has always to spend much, and, as a rule, has as small a yearly balance when he earns $10.000, as when he earned $2,000. The country physician in a small town who earns two or three thousand dollars, is often able to save something, and at the end of twenty years is generally the possessor of house, land, and perhaps other property. But in small and large cities, the expense of living grows with practice, and the difficulty of saving does not lessen as years go by. Hence he can no more afford to pay a direct tax than his apparently less prosperous brother.

The income tax is, therefore, peculiarly unjust and oppressive to the medical profession. There is a large number of physicians, also, whose incomes range about four thousand dollars, or a little over. We trust that these gentlemen, in making out their statements for the benefit of the tax-collector, will pray for a pure heart and honest mathematics in estimating their income. When the stroke of a pen will save $80, it will require a truly Christian spirit not to make it. But even with the most honest purpose it is often difficult for the physician to say whether his income will be $3,500, or $4,500, owing to the uncertainty of payments. It would seem more just, if there must be an income tax, to let everyone pay his share. There is something a little unfair in taxing the $4,100 income and not that of $3,900.

Uræmic Coma.—Lavage of the stomach with pure water will often rouse the patient from the milder degrees of this serious condition.

Chloride of Calcium. in doses of four grains, is said to be very effective in the treatment of pneumonia.

THE NEW APPLICATION OF TUBERCULIN.

WE have already alluded to the extensive condemnation of fine herds of cattle, in this and other States, on the ground that they were tuberculous. The introduction of the tuberculin test has quite revolutionized the methods of veterinary inspectors, and led to some most surprising developments regarding the prevalence of tuberculosis. The inspector now attacks a herd with a bottle of tuberculin, and speedily finds that even the healthiest animals are apparently infected. If we may believe the reports, there is hardly a single large dairy herd in the State in which some diseased animal cannot be found. We understand that, as a rule, the tuberculin test is considered a very certain one, and that in England it has been proved correct in at least ninety per cent. of cases.

The only conclusion to be reached is that there is very little milk furnished for city consumption which does not come in some part from tuberculous cows. It must be assumed that butter and cheese are made from the same kind of fluid. Of course most of the cows who are infected have but small isolated foci of disease, and their milk is practically safe. Nevertheless, the entire elimination of tuberculosis from the cattle which supply us with dairy products, is an end most devoutly to be wished. And the public money cannot be better spent than in accomplishing this object.

TROUBLE IN A MEDICAL BOARD.

WE referred last week to the fact that the Medical Board of the Almshouse and Workhouse on Blackwell's Island had, after some futile attempts to secure reforms, applied to the Health Board for an investigation. The Health Board declined to act, and the Board of Charities and Corrections became very indignant at the alleged discourtesy of the Medical Board. The result has been the following letter from the Secretary of the Commission of Charities and Correction to Dr. Charles M. Bruce, President of the Medical Board: "SIR: I am directed by this Board to request that you will call a special meeting of your Medical Board for the purpose of expressing to us your opinion of the conduct of Dr. Le Boutillier in addressing a communication to the Board of Health requesting that Board to make certain investigations, and failing in his efforts, appealing to the press, a like action being heretofore unknown on the part of any physician connected with the department, and which is considered by this Board as an act of great discourtesy, and which shows on the part of Dr. Le Boutillier an animus rather than a desire to correct abuses.

"The action of Dr. Le Boutillier has placed him in such a position of antagonism to this Board, and his usefulness is so much impaired that his further connection with the department is not desired."

The Medical Board's side of the controversy is presented in the statement of a physician who is said by the *Evening Post* to be informed of the situation.

This physician says: "The report as drawn up for presentation to the Mayor comprises little if anything more than is contained in earlier reports to the Commission made by several committees. That of the Food Committee, of which Dr. Biggs is Chairman, was drawn on for facts, and the results of the inquiries of the Investigation

Committee furnish the rest. It is an old subject and well known to the Commissioners of Charities and Correction. It is familiar to physicians in other institutions, such as the hospitals, and this is only the first outbreak of several such Medical Boards helplessly conscious of such deficiencies.

"The whole trouble lies in this Tammany economy. If President Porter had asked for the funds he needed, he would now be in a position to let the complaint go to the Mayor. As it is, he was admonished to keep his demands down, and he did so by following the same principle that guided the Mayor in cutting down Porter's and everybody else's estimate. He sacrificed the more obscure needs of the more obscure institutions, and deviated from this rule only according to the influence with him of the heads of those institutions."

The Medical Board, at its meeting on January 29th, is reported to have sustained the general attitude taken by the Committee on Inspection.

The trouble will no doubt prove useful in securing the reforms desired, though it is unfortunate that such things cannot be done without friction and publicity.

MALPRACTICE, WITH REFERENCE TO THE LEGAL AND MEDICAL PROFESSIONS.

In a recent address before the Society of Medical Jurisprudence this subject was discussed in a convincing way by Judge McAdam of the Superior Court. He points out the common relation in many ways of the two professions to the community at large. As he says, they, in a certain sense, "live on the errors, indiscretions, frailties, and follies of the rest of the community," but there is the same implied obligation in both. Both doctors and lawyers claim possession of the ordinary qualifications of their respective professions, and are consequently bound to render at least ordinary service to their patrons.

Malpractice, Judge McAdam defines as bad or unskilful practice in a physician, or other professional person, whereby injury is caused, and is subdivided into wilful, negligent, and ignorant.

Wilful takes place when the physician purposely administers medicines or performs an operation which he knows and expects will result in damage or death to the individual under his care, as in the case of criminal abortion.

Negligent malpractice comprehends those cases where there is no criminal or dishonest object, and includes gross negligence of that attention which the situation of the patient requires.

Ignorant malpractice is the administration of treatment calculated to do injury, and which does harm, and that which a scientific medical man would know was not proper.

Malpractice can only be affirmed where the physician has set aside established principles, and neglected to employ means which are universally held to be necessary in the given case.

The various decisions which have been rendered have established certain precedents which have come to possess the authority almost of statute law. Thus, if a defendant has acted honestly, using his best skill, and has not thrust himself in the place of a competent person, it makes no difference whether he was at the time a regular physician or surgeon, or not. To constitute guilt, gross ignorance or negligence must be proved. Express malice or an intent to commit a personal or social wrong always makes the practitioner criminally responsible, etc.

It is hard to determine just what constitutes reasonable and ordinary medical skill. The conditions calling for the exercise thereof vary within the widest possible limits. Moreover, a patient's caprices may interfere with the best intentions of his attendant. Furthermore, "ordinary" skill is that exercised by the average members of the profession. The law discriminates also between rural and metropolitan practitioners. "One practising in a small town or sparsely settled country is not expected to exercise the skill and care of one residing in, and having the opportunities afforded by, a large city." This implied inferiority of the country practitioner is a legal estimate, and not that of the Medical Record, which believes that the average country practitioner is fully able to hold himself up along with his urban brother.

A mere failure to cure raises no presumption as to lack of skill. The law does not expect the physician to guarantee a cure. Errors of judgment, unless so gross as to be inconsistent with ordinary skill, impose no liability. It is different with errors of diagnosis, yet here the courts have decided that the rule of compensation "applies as well to the ascertainment of the patient's disease as to its treatment, and the fact that the physician erred as to the disease and treated the patient for one he did not have will not defeat the physician of compensation."

The decision is placed on the broad ground that every branch of medicine is not capable of assured and exact determination in practice, and that where the practitioner of customary skill cannot, with proper diligence, distinguish the nature of the disease, he is not at fault; that the physician is not a guarantor of diagnosis in cases where there is no absolute certainty in results."

We have alluded to only a few of the many interesting points which are touched upon in Judge McAdam's address. It is comprehensive and yet concise. The numerous references to legal decisions bearing upon the matters discussed render it a valuable reference paper for anyone who desires to pursue the subject further. The entire address may well be read with great profit by every practitioner.

THE MEDICAL TREATMENT OF THE PHYSICIAN BY THE PHYSICIAN.

The question has been recently discussed as to whether medical men should charge their professional brethren for services rendered. *Gaillard's Medical Journal* asserts peremptorily that "Such a course of conduct is wholly damnable. There is no member of the medical profession, however humble his position in life may seem to be, who may not some time have it in his power to make adequate return for medical services rendered to himself or to his family, either to him who has rendered them or to some one dear to him." In other words, don't charge because some day you will in some way receive your *quid pro quo*.

We should say that our esteemed contemporary's views are neither very elevated nor very sound. We know of a number of physicians who can hardly be considered "damnable," but who insist on paying for services rendered, and who accept fees in return. The old way has a

delightful sentiment in its support, but does it work well? Ask any doctor who has been seriously ill, and who has, by the grace of God, got well while under the care of half a-dozen of his good-natured *confrères*. The doctor, when sick, is often in a desperate strait, since many wish to help him, while few care to take the exclusive responsibility. We have heard of a well-known physician in this city who wanted a careful examination and a candid diagnosis of his somewhat obscure ailment. After getting a number of easy diagnoses, friendly opinions, and off-hand prescriptions, he went to another city, took his turn in the waiting-room, paid his fee, and got what he desired.

The question at issue is not one to be settled by a fixed rule or by sentiment alone. In most cases, undoubtedly, medical services should be rendered freely, and so they are; for doctors are generous and kindly men, but sometimes the ailing physician is able and anxious to pay, and sometimes the time and labor required by the medical service are so great that it is an imposition on the medical brother, and one that cannot be settled by the presentation of a picture-book or a paper-cutter on Christmas. For our part, we do not recommend or advise that doctors should charge their colleagues for treatment; but we do advise the doctor who is ill to pay if he can, whenever his illness calls for a serious amount of work and attention.

"DOC.," THE CORNER DRUGGIST.

WHETHER it is because of the financial stringency through which we are passing, or whether other influences are being felt, there appears just now to be a decided increase in the amount of medical knowledge demanded and furnished in the drug store. This does not apply alone to the smaller stores in crowded districts, nor to the druggist in the country, where often "Doc" has a well earned diploma to back up his possession of the title, and his right to prescribe as well as to dispense.

Considering the pleasant business and social relationship habitually maintained between doctor and druggist in this city, it is the more to be regretted that duty requires us to make a vigorous protest against what appears to be a growing tendency on the part of some apothecaries, even in the best portions of this city, to usurp the prerogatives of the properly qualified medical adviser. The physician can have no better friend and ally than the honest dispenser of his prescribed remedies, and by reason of the security and satisfaction he has in the belief that pure drugs, accurately weighed and skilfully combined, will be delivered on his written order, he feels that he is indebted to the extent of a certain amount of moral and financial support.

The appreciation, on the physician's part, of this conscientious co operation may be shown in many ways, and the prosperity of this or that pharmacy can often be clearly traced to practitioners who have given it their support and commendation. When dishonesty enters the druggist's door, enmity must replace the doctor's friendliness.

Acting the part of the physician is one form of dishonesty, and a bad one. The druggist without a medical diploma has no more right to heal the sick than any other irregular or quack. Perhaps it is because we have done so much to rid the city of the latter undesirable class that the druggist finds his field of would-be usefulness increasing.

The habit of calling upon "Doc" for advice in "slight ailments" gradually leads to weighty trans-counter consultations and examinations in the back-room, to say nothing of the minor surgery practised, and indeed urinary analysis made in some accommodating shops. When the financial loss to the physician from all this is taken into consideration, together with the injustice done him in having his successful prescriptions passed along for the benefit of "similarly affected," and the injurious results arising from the unauthorized refilling of prescriptions, one must needs wonder that no decided stand in self-defence has been taken. To be sure, the increasing use of tablets has dealt the druggist, as well as the homœopathist, a staggering blow, and in some instances the doctor's office has been stocked with remedies in convenient form from motives of self-protection. Whatever falling off there may have been in the prescription department from this growing custom, which is much a matter of individual taste and expediency, it in nowise excuses the apothecary for turning doctor unless he does it in the good old way, in which event we will welcome him with encircling arms. Just as in the dispensary question, it is against the abuse, and not against the institution, that weapons must be taken up. The pharmacy is a necessity, the honest pharmacist a blessing. Let us hope that moral suasion will be the only weapon needed to bring "Doc. the prescriber" back where he belongs, in the ranks of a most honorable army.

THE INDICATIONS FOR BLEEDING.

SIR BENJAMIN WARD RICHARDSON is rather fond of bleeding, and in his *Æsclepiad* he has published several articles describing his experiences and his successes. In the last issue of this journal he tries to indicate the moment for bleeding; and the conclusions to which he arrives are these: One may bleed—

a. In acute spasmodic seizures, as in spasm of croup, in colic, and in angina with symptoms of oppression from distention of the right side of the heart with blood.

b. In acute pain, membranous or spasmodic, as in sudden pleuritic or peritoneal pain, or in pain from passage of a calculus, hepatic or renal.

c. In acute congestions of vascular organs, as of the lungs or brain, apoplexies.

d. In cases of sudden shock or strain, as after a fall or a blow, sunstroke or lightning shock.

e. In some exceptional cases of hemorrhage of an acute kind unattended by pyrexia.

This, it seems to us, makes rather a poor showing for venesection. It means practically that bleeding is only needed in uræmic convulsions and sanguineous apoplexy, for in most of the other conditions morphine or some heart stimulant would answer as well, if not better.

The fact is, bleeding has gone forever from ordinary therapeutics. This is not because it is useless but because modern science has devised better things as substitutes. Bleeding was legitimate and effective in its day, and would be useful now if our materia medica had not been so enlarged. We have given it up, not because of a change of fashion, but because we have outgrown it.

News of the Week.

To be Examined After Seven Years of Service.—Dr. Adler Blumer, who was appointed Superintendent of the State Lunatic Asylum in Utica, on December 29, 1886, in place of Dr. Gray, deceased, has been notified to appear before the Civil Service Commission for a non-competitive examination to show his fitness for the place. Governor Flower, who has approved of this action is reported to have said :

"In 1886 Dr. Blumer was appointed Superintendent at the Utica State Hospital. The State Civil Service Commission was notified of the appointment at the time and asked to take the necessary action in the matter. Nothing was, however, done on the part of the Commission. In 1886 the office of Superintendent was in the non-competitive schedule. In 1888 it was placed on the competitive schedule; therefore Dr. Blumer should be allowed to take a non-competitive examination, the same as he would have taken in 1886, had the State Civil Service Commission carried out the law."

If the position taken by the Governor is the correct one, every medical or other officer holding a State appointment under the old law is liable to receive the same treatment. Dr. Blumer has held his present position acceptably and without previous protest since 1886. Thus he has been acknowledged as entitled, officially and otherwise, to the position for seven years before the Civil Service Commission calls him to account. These are curious facts which every State officer should thoughtfully consider, especially if he be a medical superintendent of a State asylum, and opposed to the Lunacy Commission's doings.

There is no doubt that Dr. Blumer can pass any fair examination, but the principle of the thing, viewed particularly at this time and under present circumstances, is not beyond suggestive comment and honest criticism.

A Hospital While You Wait.—The Metropolitan Asylums Board of London recently had a hospital built in nine weeks, with wards all complete, beds for 400 patients, every hygienic and sanitary appliance, corridors, kitchens, and consulting-rooms. This hot haste was to enable the authorities to cope with the ever-increasing number of fever cases that were crowding in upon them. Accommodation, apart from that for the 400 patients aforesaid, is provided for 40 "charge" nurses, 50 assistant nurses, and 76 female servants.

Hysteria and Marriage.—The belief is as old as Hippocrates that hysteria is cured by marriage. But Dr. Wythe Cook (*American Journal of Obstetrics*, December, 1893) finds from his experience that in most cases of dysmenorrhœa and hysteria among single women marriage aggravates the disease. Hysteria is by no means cured by marriage, dysmenorrhœa often returns after pregnancy.

Abuse of Hospitals in Paris.—In view of certain gross cases of abuse of the benefits of hospitals by well to do persons which have recently come to light, the Paris Municipal Council has appointed a committee of fifteen of its members to inquire into the organization of the Assistance Publique. The committee is instructed to devise some means of preventing the abuse of medical charities by persons able to pay for advice.

The Tenth Annual Meeting of the Fifth District Branch of the New York State Medical Association will be held in Brooklyn on Tuesday, May 22, 1894.

The Harvard Medical Society of New York City.—At the meeting, held on January 27th, the following officers were elected for 1894: *President*, Reynold W. Wilcox, M.D.; *Vice President*, Royal Whitman, M.D.; *Secretary* and *Treasurer*, Dillon Brown, M.D.; *Executive Committee*, J. Winters Brannan, M.D., Frank H. Daniels, M.D., and Howard Lilienthal, M.D.

Death of Dr. Eugene Tiesler.—At a meeting of the State Board of Medical Examiners, held at Trenton, N. J., Monday, January 22, 1894, the following was offered and unanimously adopted: "The members of the State Board of Medical Examiners of New Jersey desire to express their profound sorrow for the death of their associate, Dr. Eugene Tiesler, which occurred at Frankfort, Germany, January 19, 1894. They will ever cherish a kindly remembrance of his uniform courtesy and high sense of honor, his usefulness and conscientious fidelity to duty. They tender to his family their sympathy, and inscribe on the minutes of the Board this tribute of respect to his memory."

Death of Dr. Frank D. Beane.—Dr. Frank D. Beane, of this city, died on January 6, 1894, of remittent fever, after two weeks' illness, at Lake Worth, Fla., in his forty-third year. Dr. Beane was fitted by studious habits, a fondness for scientific work, and special predilection for the profession he had adopted. His health, never robust, was undermined by the arduous duties of general practice, and of late years he had paid special attention to diseases of the eye and ear, in which he had attained a reputation that permitted his passing the winter season in the South, and promised a future of greater leisure and assured longevity. He had many sterling traits of character which endeared him to those with whom he was associated, and by whom his early demise is greatly deplored. An exemplary life was closed with no fear of death in the confident hope of immortality.

The State Board of Medical Examiners.—It is announced that Governor Pattison has selected from the membership list of the State Medical Society the following gentlemen as members of the Pennsylvania State Board of Medical Examiners, representing the regular medical profession: H. G. McCormick, of Williamsport, for three years; Henry Beates, Jr., of Philadelphia, for three years: W. J. R. Kline, of Greensburg, for three years: A. R. Hulsizer, of Philadelphia, for two years; N. S. Foster, of Pittsburg, for two years: J. E. Silliman, of Erie, for one year; and Samuel W. Latta, of Philadelphia, for one year. The President of this Board, together with the Presidents of a Board of Homœopathists and a Board of Eclectics, the Lieutenant Governor, the Attorney-General, the Secretary of Internal Affairs, and the President of the State Board of Health, constitute a Medical Council, to which will be submitted the questions proposed to be asked applicants for license to practise medicine in the State of Pennsylvania: and from these the Council will select the questions to be asked, except in the departments of materia medica, therapeutics, and practice of medicine. The Council will meet twice a year and supervise the examinations of the State Boards, and issue to the successful applicants licenses to

practise medicine and surgery. The first meeting of the Examining Boards will be held on the first Tuesday of April.

A National Bureau of Health.—If present indications lead aright, the long-deferred organization of a National Bureau of Health will soon be a reality. The people seem to have awakened to the necessities of the case, and prompt action may be expected. The proposed measure has received the indorsement of nearly every medical society in the country, and has encountered no real antagonism, and large numbers of petitions have been presented in its favor. The only fear is that the legislation may be pushed aside by other less important matters. It is to be hoped, however, that the agitation will be kept up until the bill that is now before both houses of Congress has been finally passed. It is believed that the President, the Secretary of the Treasury, and administration officials generally, are favorably disposed toward the bill. The President, in his annual message to Congress, strongly recommended additional safeguards for the public health such as are proposed by this measure.—*Medical News.*

A Four Year Course at the National Medical College.—At a meeting of the Faculty of the Medical Department of Columbian University, of Washington, D. C., held on April 11, 1893, it was unanimously agreed to make a four year course of study necessary before graduation. This measure went into operation at the beginning of the present session of 1893–94. Each of the four courses covers seven months of lectures.

The Husband's Liability for the Wife's Medical Expenses.—The Supreme Court of California recently ruled that where the husband is liable for his wife's support, the wife's estate cannot be charged for medical services, medicines, and nursing which he secured for her in her last sickness, but that he alone is liable for them.

The Brooklyn Health Commissioner's Office.—It is announced that the new commissioner, Dr. Z. Taylor Emery, has appointed Dr. Richard M. Wyckoff deputy commissioner, Dr. George E. West secretary, and Mr. Alexander H. Van Cott counsel.

The Greatest Consultation in History.—The veracious daily press states that the mother-in-law of the Mikado of Japan has recently been ill. She was attended by 423 physicians, but in spite of that has pulled through. The 423 medical men hadn't much to say as to the cause of the lady's illness, but a Buddhist priest of ingenious mind declared that it was owing to the introduction of railroads. His logic was simple. Before there were railroads, she was well. After there were railroads, she was ill. What could be more clear than the conclusion he drew?

Literary Notes.—The late Dr. Samuel Guttmann is succeeded in the editorship of the *Deutsche medicinische Wochenschrift* by Professor A. Eulenburg and Dr. Julius Schwalbe. Professor Landouzy is the Editor in Chief of the *Presse Médicale*, the most recent addition to the already formidable list of medical journals published in Paris. Among his collaborators are MM. Brun, H. Roger, Letulle, Lermoyez, and de Lavarennes. A monthly journal devoted to hydrotherapy, electropathy, and mechanical treatment, will shortly be published by Seitz and Schauer, of Munich. The editor is Dr. A. Krüche, who will have the advantage of the active collaboration of Professor Eulenburg, of Berlin, Professor Rosenbach, of Breslau, Dr. Barwinski, of Elgersburg, and a number of well-known hydrotherapeutists. The *Psychological Review* is the title of a new quarterly published in this city by Macmillan & Co., and edited by Professor J. Mark Baldwin (Princeton) and J. McKeen Cattell (Columbia).

A Statue to Charcot.—A committee has been formed for erecting a statue to M. Charcot. MM. Brouardel, Pasteur, and Gréard are presidents. M. Masson, 120 Boulevard St. Germain, is treasurer. The General Council of the Seine has given $100.

The Cincinnati Obstetrical Society, at its regular annual meeting, held at the residence of Dr. R. B. Hall, elected the following officers for the ensuing year: *President,* Dr. T. P. White; *Vice-President,* Dr. R. B. Hall; *Secretary,* Dr. E. S. McKee; *Corresponding Secretary,* Dr. W. D. Porter; *Treasurer,* Dr. G. E. Jones. The Society resolved to meet the first and fourth Thursdays in each month instead of monthly as formerly. Steps were also taken to secure a permanent place of meeting instead of meeting at the residences of members as formerly. The past year has been a very valuable one to the Society.

Lunacy Administration in America.—We had occasion some months ago to indicate, with a force of language which subsequent events have justified, the iniquitous and cruel policy of the Lunacy Commission of the State of New York. It is a question of men and motives, and the average citizen needs no expert evidence to guide him in getting to the bottom of the matter. The facts are plain business facts, that may be called jury facts, and if the average intelligence of the State of New York is not competent to come to a sound jury decision on the matter we are much mistaken. It seems incredible that in this *fin-de-siècle* age the State of New York, of all places on earth, should be completely at the mercy of three men in respect of its lunacy administration. One can scarcely conceive it possible that these three Commissioners have legally vested authority to control the commissariat of the eight State hospitals for the insane directly from head-quarters; that the managing boards of these hospitals may submit schedules of requirements to the Central Board, but cannot contract for or order supplies for their own asylums. These institutions have been hampered and harassed in their work by the pettifogging practices of the Lunacy Commission. In one asylum the patients were deprived of oatmeal for a month because of failure to specify the particular brand desired, though quality and price were mentioned. Striking requests for nails, timber, lime, and bricks had stopped necessary repairs. In another case the complaint is, "We have gone weeks without tea, and then got permission to buy two pounds," etc. A conference of Asylum Managers and Superintendents at New York revealed these and other delinquencies of the Lunacy Commission. Numerous instances were given of the positive hardships suffered by the insane in the New York State Asylums, and to cut off the supply of tobacco is but one of many illustrations of the scandalous excisions perpetrated by the red-tape machinery of the head-quarters at Albany.—*Medical Press and Circular.*

Society Reports.

BIOLOGICAL SOCIETY OF PARIS.

Experimental Production of Gastric Ulcer.—Drs. Hallion and Enriquez presented at the last meeting the results of their researches on the experimental production of gastric ulcer. They found that when pure cultures or the toxine of the diphtheritic microbe was injected subcutaneously, that death followed in from three to fifteen days, and in post-mortem examination the gastric mucous membrane was found covered with ecchymoses. The submucous coat of the stomach presented considerable congestion beneath where the ecchymoses appear in the mucous membrane itself.

Toxicity of Blood-serum.—Drs. Leclainche and Remond presented a note on the toxicity of the blood-serum, mentioning particularly that the toxicity varies for different animals according to their species; for instance, the serum of the dog is very toxic to the rabbit, the serum of the horse is very slightly so. The serum of anæmic dogs is less toxic than when the blood is rich.

Structure of Sympathetic Ganglia.—Ramon y Cajal presented the following conclusions on the structure of the sympathetic ganglia: 1. The visceral ganglia are constituted by the multipolar cells, the expansions of which, after many ramifications, pass into the plexus which terminates in muscular fibre or glandular cells. 2. All ganglia possess fibres of prolongation which continue perhaps with the fibres of the grand sympathetic, and likewise collaterals, which terminate in nerve cells. 3. Chiasma represent not alone a point of inter crossing, but also a point of bifurcation for the nerve-fibre prolongations, and for the expansion of visceral ganglionic cells. 4. There exists no anastomosis between the cells of the visceral ganglion, or between prolongation fibres, nor between the collaterals. The same probably holds for the interstitial cells.

A New Streptococcus.—MM. Doleris and Bourges presented notes on a new streptococcus, occurring in chain form and found in the pus of a pelvic abscess. This organism does not liquefy gelatine or change bouillon. It is inoffensive when injected into the rabbit. It is thus analogous to the coccus recently described by Marot.

The Pathogenesis of Scarlatina.—M. Ricochon made some observations on the pathogenesis of scarlatina. He related first a case of irregular scarlatina which desquamated on the sixth day. At the time of the appearance of the eruption the patient developed a painful sore on the leg, which became the point of departure of a suppurative lymphangitis. Two months later he succumbed. A woman came to visit this patient twelve days after the advent of his illness. She contracted an erysipelas of the face, which ran an ordinary course. Nine days after, her husband, who had a local abrasion on the finger, had an attack of adenitis axillaris suppurativa. A few days after a newly confined woman came to the village where these patients resided and was taken with scarlatina. In the meantime a debilitated young man who visited the first patient, suffered an attack of lymphangitis from which he recovered, and a second friend, who came to visit him from an adjoining village, had an attack of erysipelas with hepatic complications and albuminuria.

M. Ricochon thinks these facts presumptive evidence in favor of the identity of the poison in these different affections.

THERAPEUTIC SOCIETY OF PARIS.

Intoxication from Salicylate of Soda.—Dr. Huchard cited a case where the administration of salicylate of soda in one of his patients was followed by the phenomena of intoxication. The solution was old, probably concentrated.

ACADEMY OF MEDICINE OF PARIS.

Dyspepsia and Constipation.—Germain Sée considers that most of the conditions treated as dyspepsia, dilatation of the stomach, etc., are really sluggish conditions of the enteric mucous membrane due to constipation. He insists on the mechanical *rôle* of this constipation in causing hemorrhoids, hernias, vesico-uterine tumors, hypertrophy of prostate, etc. He recommends that the constipation be overcome without purgatives, but that simple laxatives like senna, hydrastis canadensis, castor-oil or large doses of olive oil be used. To relieve the pain attending these conditions of the mucous membrane of the intestine, he recommends:

℞. Calcium brom.,
Calcium chlorid. ..... āā 50 gm.
Aquæ. ..... 500 gm.
Sig.: Dessertspoonful in twice its quantity of water at meal-times.

For particularly acute crises of pain, he uses:

℞. Menthol. ..... 10 gm.
Spts. vin. rect. ..... q.s.
Aquæ des. ..... 180 gm.
Sig.: Teaspoonful as indicated.

To combat fermentation and tympanism, he recommends phosphate of soda ℈ ij. to ℈ iij., salicylic acid, gm. iij. to vi., and borax. To combat auto-intoxication, he regulates the diet.

MEDICAL SOCIETY OF THE HOSPITALS (PARIS).

The Pathogenesis of Floating Kidney.—Dr. Le Gendre points out the following etiological factors in the pathogenesis of floating kidney: 1. It exists almost always in females. 2. It is exceptional in children. 3. It rarely shows itself in young girls before adolescence. 4. It is most frequent in females who have been pregnant. 5. It frequently coincides with atonic gastro intestinal dyspepsia and dilatation of the stomach. 6. It exists most frequently associated with lax abdominal walls, due to any cause. The corset probably has something to do with its frequent occurrence in women, and he recommends that children who present symptoms of nervousness and atony of the gastro-intestinal canal, should be made to wear specially constructed corsets which will not constrict the base of the thorax.

Non-exudative Tubercular Peritonitis.—M. Demailer reported a case of non-exudative tuberculous peritonitis treated by laparotomy. The patient presented the symptoms of peritonitis with diarrhœa. On opening the abdomen the parietal portion of the peritoneum was found adherent to the visceral portion, the intestines were matted together, and innumerable granular surfaces studded the peritoneum. Drainage-tube was introduced, and the cavity washed with a boric-acid solution. Twelve days after the operation the patient was quite well. This amelioration persisted for a month. Then the bad symptoms reappeared concomitantly with a fecal fistula, and the patient died of inanition and exhaustion two months after the operation. He remarks that the non-exudative peritonitis, contrary to the exudative forms, should be looked on as non-operable.

Aphasia and Pneumonia.—Chantemesse has seen transitory aphasia of an ataxic type occur during the course of pneumonia. It shows itself on the second or third day of the disease, either suddenly and without loss of consciousness, or preceded by vertigo, headache, and paræsthesia of the right side of the face and right upper extremity. Accompanying it in every case was paresis of the right facial nerve and some weakness of the right upper extremity. The course and termination of the pneumonia is seemingly not influenced by the presence of the aphasia. The duration of the aphasia is from one hour to four or five days. The facial paresis lasts about the same time, but the arm is slower in recovery. The cause of the aphasia is probably the action of the toxine

of the pneumococcus on the central nervous system or on the contractility of the blood-vessels.

M. Nicati spoke of a new treatment for glaucoma by means of sclero iridotomy. To his mind the cause of glaucoma is the retention of the aqueous humor. The only efficacious treatment is sclero-iridotomy, permitting the escape of the aqueous humor. In spontaneous glaucoma perforation of the iris is absolutely necessary. In secondary glaucoma simple sclerotomy suffices.

PATHOLOGICAL SOCIETY OF LONDON.

Myo-carcinoma of Uterus.—Dr. Dickinson showed a specimen of a tumor of the uterus, which appeared to have begun as an ordinary fibro-myoma, but latterly to have assumed a character which could only be described as malignant or sarcomatous. The patient was a single woman, aged forty-eight, who had noticed its growth for twelve months. The tumor, about the size of a melon, situated in the anterior wall of the uterus, caused death by exhausting discharge and pressure. Externally it resembled a fibroid, both ocularly and with the microscope; centrally it was soft and yellow. The soft part had broken into the cervical canal and through the back of the uterus into the peritoneal cavity, forming a sprouting hemorrhagic growth, which on microscopical examination was seen to consist of short spindle-cells with enormous nuclei. Between the fibroid part and the sprouting part the cells showed in a state of transition between the two extremes.

Mr. A. Doran remarked that he had seen many cases where a myoma became clinically malignant, setting up ascites and killing the patient without growing very large.

Sacculated Hypertrophied Bladder.—Mr. F. C. Wallis showed a specimen of sacculated hypertrophied bladder which had ruptured through a saccule into the portæ vesicæ, and thus produced all the symptoms of a distended bladder, the escaped urine being extra-peritoneal.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 18, 1894.

D. B. St. John Roosa, M.D., President, in the Chair.

Bureau for Nurses.—Dr. Landon Carter Gray, President of the newly appointed Committee on Bureau for Nurses, stated the purposes for which the bureau had been established, the manner in which it was proposed to carry out the work, and asked for an appropriation the first year of $500, a room in the Academy building, and permission to put in a telephone. The plan had been in successful operation in Philadelphia, Brooklyn, and Boston, and the income had exceeded the expenses in those cities by a considerable sum; the same could be expected in New York City after the first year. The Committee had inquired into the workings of the system in the cities referred to, and it was proposed to have a superintendent in a room in the Academy; nurses were to be recommended by physicians; they were to be assessed $2 a year; when the services of one were requested the patient was to pay to the bureau $2, and from this income it was expected to meet the running expenses. On motion the Committee's request was granted. The President of the Academy said he anticipated great increase of usefulness of the Academy from this step.

Observations on Excessive Intestinal Putrefaction.—Dr. C. A. Herter read a paper on this subject. Not long since, he said, attention had been called to excessive intestinal putrefaction in epileptics, and observations were then made which went to show that sometimes in epilepsy the appearance of such excessive putrefaction determined the epileptic seizure. The character of the observations, which had been continued by the author, related, 1, to the evidence of the existence of putrefactive processes in the intestine; 2, the clinical conditions in which putrefaction occurred in excess; 3, the principles which entered into the management of cases where excessive putrefaction was present.

In the first part of the paper the author reviewed the evidence pointing to the fact that the presence of ethereal sulphates in the urine was due to putrefactive changes in the proteid substances in the intestine, and the amount of such sulphates was indicative of the extent of the putrefactive process. The only source of error was in the fact that certain drugs, as salol, would give rise to ethereal sulphates, and their presence might also be determined by an undrained abscess in the body. As a rule, however, these sources of error could be excluded in any given case.

The most important of the ethereal sulphates was what had been called indican, which colored the urine indigo-blue when treated with hydrochloric acid. The quantity of indigo blue consistent with health was believed to be very small. Even moderate amounts were likely to be associated with digestive disorders and might properly be regarded as abnormal. If the quantity of indigo-blue was greater than five milligrammes in twenty-four hours, which amount would yield a distinct reaction by the Jaffé test, it might be regarded as pathological, and, as a rule, due to putrefaction of proteids in the intestine. The possible relation of certain bacteria to the intestinal putrefaction was only alluded to in the paper.

The symptoms ordinarily referred to intestinal indigestion might be grouped under two heads—local symptoms due to direct effect upon the bowel and its function, and remote symptoms due to absorption of intoxicants, etc. Of the local symptoms, the most important was flatulence. With it was associated abdominal pain. In his observations it was usually in relation to the amount of indican in the urine, yet indican was often present when there was no flatulence. In one class of cases the indican disappeared with control of flatulence, in another it did not. A change of diet to a form of nitrogenous, which was little likely to undergo putrefaction, was frequently attended by disappearance of the indican from the urine. In some cases, however, this effect was not observed.

Among the remote symptoms of intestinal putrefaction were malaise, lassitude, aversion to exercise, involuntary muscular twitching, especially in the back, flushing of the face, cold and moist extremities, irregular and habitually rapid heart, perhaps attacks of tachycardia, drowsiness during the day, hypochondria, impaired appetite, loss of weight, etc. Most of these symptoms were those of neurasthenia. It was not yet clear what was the cause of the remote symptoms.

The author had studied intestinal putrefaction in forty cases of epilepsy, eight of acute melancholia, and eight of chronic Bright's disease. In the cases of epilepsy about two-thirds of those of grand mal showed distinct evidences of excessive intestinal putrefaction, and in a few there seemed to be a direct relationship between this and the seizures, and in some the seizures were checked by controlling the intestinal putrefaction. Six of the eight cases of Bright's disease showed a marked increase in the ethereal sulphates. In some cases of simple anæmia there was increase of the ethereal sulphates, in some there was not. In two cases of Basedow's disease the sulphates and indican were largely increased, the same of three cases of urticaria and in catarrhal jaundice.

Treatment of Excessive Intestinal Putrefaction.—The object of treatment was not to check all intestinal putrefaction and to render the intestine free from bacteria, but rather to limit the changes within normal bounds as indicated by the condition of the urine. Limitation of the amount of putrefaction might be undertaken with reasonable hope of success. The methods were by drugs and hygienic measures, especially diet. The drugs which first suggested themselves were those supposed to restrict the growth of bacteria in the intestine, the so-called intestinal antiseptics; but there was

not much to be said in their favor, either *a priori* or after clinical experience. Their effect upon the urine, however, had been studied, and it had been found that some of them, as resorcin and salol, were eliminated as ethereal substances in the urine, so that their value could not be tested in this way. Many of the symptoms of pain and flatulence were often relieved by large doses of salol. Both hydronaphthol and beta-naphthol appeared to have no effect in checking the ethereal sulphates in the urine when administered in doses which could be well borne. Salicylate of soda, fifteen grains three times a day, might be safely recommended as a valuable intestinal antiseptic. In some patients it tended to bring the ethereal sulphates down to the normal. If reduced to below ten grains it seemed to be of little service, and many people could not take more. There was conflicting evidence as to the effect of calomel on the ethereal sulphates, but probably it had no effect in intestinal putrefaction except as a cathartic.

Regarding Diet.—A given amount of nitrogenous food in the form of milk and meat was more easily digested than the same amount in oatmeal, beans, peas, and a mixed diet. The easiest way to reduce the ethereal sulphates when in excess was to put the patient on a diet of which milk was the chief or exclusive constituent. The evil effects of physical over-fatigue on digestion should be borne in mind, also that of sexual excitement and masturbation.

Regarding the treatment of epilepsy based on a knowledge of intestinal putrefaction, it must be admitted that the results had not been very encouraging, especially in well-established cases. In infants the symptoms sometimes disappeared for months, sometimes as long as the patient had remained under observation. In all recent cases of epilepsy, in children especially, attention should be paid to the intestines.

The following conclusions were reached: 1. An excess of the ethereal sulphates in the urine is evidence of excessive putrefaction of the proteids in the intestine. There are two exceptions to this statement: *a*, In the case of suppuration without free drainage; *b*, where certain drugs, as creosote and salol, have been administered. 2. The indigo-blue of the urine is not necessarily proportional to the total ethereal sulphates, and is to be regarded as due to a chemical formation by putrefactive change. 3. The regular occurrence of more than a trace of indigo-blue is to be regarded as pathological, although in robust persons there may be but little evidence of digestive disturbance. 4. The presence of indigo-blue in the urine of infants is no evidence of a tubercular process, as has been supposed by some. 5. Intestinal flatulence is more often associated with intestinal putrefaction than any other symptom of intestinal indigestion. 6. Both constipation and starvation may increase the putrefactive products in the urine under certain conditions. 7. Epilepsy, acute melancholia, and chronic Bright's disease are usually associated with excessive intestinal putrefaction. 8. The treatment of excessive intestinal putrefaction by means of drugs is at present unsatisfactory. 9. The use of rare beef and milk, and the exclusion as far as possible of vegetable nitrogenous food, are important means of reducing excessive intestinal putrefaction and of relieving the symptoms of intestinal indigestion. 10. The relief of the intestinal symptoms cannot be ascribed wholly to the effect of milk- or beef-diet on intestinal putrefaction. 11. The treatment of epilepsy by measures directed to the intestinal condition leads in many cases to a reduction of the number or severity of the attacks and marked improvement in the health. 12. It is possible that in children the early seizures are sometimes determined by putrefactive excess, and treatment directed thereto may improve or even cure the patient before the epileptic habit has become established.

Dr. L. C. Gray thought the author had presented a very valuable and original paper upon one of the phases of nervous troubles, which promised to throw some light upon a very obscure class of cases. Time would not permit of his giving in detail certain observations made by himself upon the urine during the past few years, but because of the bearing which they had upon certain nervous troubles he hoped to lay them before the Academy in a paper at no distant date. His studies on the urine, however, had not been limited to the indications of intestinal putrefaction, but he might state in general terms at present, that they went to confirm the conclusions reached by Dr. Herter. Regarding certain drugs, perhaps his results had been somewhat more satisfactory. Salol had relieved some severe cases; others had been relieved by a combination of salol, bicarbonate of soda, and pancreatin. In some nothing could be done to correct the intestinal putrefaction and symptoms arising therefrom until a cathartic of calomel had been administered. The most remarkable agent, on the whole, had been the subgallate of bismuth, but in some cases it failed entirely. As a rule, where there had been reason to make a diagnosis of intestinal putrefaction, the patients had been more successfully relieved by a combination of disinfection with a slight laxative, than by disinfection alone. The laxative which he usually employed was Rochelle salt. It was difficult to leave out of consideration the amount of uric acid in the urine in both functional and organic nervous diseases, and he had found, when he had studied the urine with regard to the presence of this and other factors, that when he gave an exclusively nitrogenous diet the uric acid increased, and, according to the case, certain symptoms became aggravated; whereas, if the patient were put on a vegetable diet, the indican in the urine increased, so that he found himself placed, as it were, "betwixt the devil and the deep sea."

Dr. Charles L. Dana thought Dr. Herter deserved much credit for pushing his inquiries along a line which involved so much careful and diligent research. Neurologists would do well to profit by such investigations. He had himself, for several years, borne in mind the influence of uric-acid excess and that of intestinal putrefaction in the treatment of nervous diseases. He had found that excess of indigo-blue and of uric acid were apt to go hand in hand, and were often present in epilepsy and neurasthenia in adults. In the therapeutics of intestinal putrefaction he had also met with variable results, both as to the effects on the primary condition and on the nervous affection from which the patient might be suffering. It was well known that in neurasthenia attention had been turned first to one thing, then another; at one time it was the uric-acid theory; at another, the lithæmic; at another, eye reflexes; at present, intestinal putrefaction. While a single explanation had not been found for all cases, he thought benefit was being derived from the total of our observations in these several directions. He also had obtained better results from combined laxatives and antiseptics than from the latter alone. Naphthalin had acted like magic in some cases of neurasthenia and migraine.

Restricts Meat in Epilepsy.—Dr. William H. Thomson had long thought that more light could be thrown upon the subject of functional nervous diseases by chemistry than by pathological anatomy. The striking feature of intermittency pertaining to functional nervous diseases, such as epilepsy and migraine, certainly deserved study. It was in marked contrast with what was observed in organic nervous diseases. Considering these facts, he had always felt a great interest in the question of auto infection from the alimentary canal in the functional nervous disorders. For years it had been his custom to inquire carefully into the condition of the intestinal functions in epileptics. One of the first questions which he put was, whether the patient's breath was offensive before, during, or after an attack, and in about thirty per cent. of the cases the friends had given an affirmative answer. In about forty per cent. there had been evidence of flatulence and other intestinal disturbance: in a small per cent. there had been diarrhœa. Treatment based on this knowledge had given him considerable encouragement.

His experience with intestinal antiseptics had been much like that of the previous speakers. Salol had often been useful, but in efficient doses often caused gastric disturbance, so that he had come to give it in smaller doses combined with other antiseptics. On the whole, benzoate of soda was his favorite. Bismuth had shown very marked power over intestinal putrefaction in that it was almost a sure preventive of diarrhœa when given in large doses throughout typhoid fever. If diarrhœa were already present, a calomel purge would almost uniformly stop it Regarding the diet of epileptics, he had for years been in the habit of cutting off nearly all flesh food, relying on milk for the nitrogenous element, especially in the form of matzoon or fermented milk, a moderate amount of vegetable food. Peas and beans increased albumin in the urine in chronic Bright's disease, and were apt to aggravate any renal trouble. Probably beans increased intestinal putrefaction, aggravated kidney troubles, and enhanced the dangers of convulsive nervous disorders. There was a great difference between nitrogenous food as found in milk and as found in flesh. The fact that almost all carnivorous animals died in convulsions, and that the feline tribe were peculiarly liable to fits, gave some reason for believing that a meat diet was not favorable for epileptics.

Intestinal Putrefaction in Children Due to Carbo-hydrates.—Dr. L. Emmet Holt said a great many children, three or four years of age, were brought to the clinics, who had a spare body, an immense abdomen, and who suffered from chronic constipation. Usually the history was a food composed almost exclusively of oatmeal and carbo-hydrates. The treatment almost uniformly followed was to take away most of the starchy food, and to put the patients at once upon peptonized milk and raw or rare meat. If necessary a dose of calomel was given every three or four days. Generally the constipation was pretty well controlled by the diet, particularly if the milk were not only well peptonized but contained a little more than four per cent. fat. The result was gain in weight, diminution of flatulence and in the size of the abdomen, and disappearance of a large number of nervous symptoms.

Dr. Herter closed the discussion.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, January 5, 1894.

George L. Peabody, M.D., Chairman *pro tem.*

The Caisson Disease. — Papers were read on this subject by Drs. Andrew H. Smith and W. Gilman Thompson (see pages 130 and 133).

Dr. Smith said that since writing his paper a very interesting case had entered the hospital, in which a large area of the skin was covered by a mottled eruption of a little lighter hue than that of port wine. The spots would disappear after a little gentle friction and did not return, at least not for a considerable length of time, and then in a less marked degree than before. This showed that the blood was still in the capillaries and could be moved on into the general circulation. There were some spots, however, that could not be made to disappear, showing that they were due to true ecchymosis, the blood being outside the vessels, in the tissues. A man when seen in the caisson was pale, having the appearance of tallow, the pressure driving the blood from the surface, during which time the vessels lost to a considerable degree their power to regulate their calibre, so that when pressure was removed they became over-dilated, and if the change were sudden, the blood entered the tissues and formed ecchymotic spots.

Dr. Abbe inquired whether visitors to caissons were ever affected.

Dr. Smith replied that it was exceedingly dangerous for any man who had never been in a caisson to go down and stay more than a few minutes. A student once went into one where the pressure was only two atmospheres, and had a pretty severe attack of the caisson disease after a brief sojourn.

Dr. Abbe said that when the Brooklyn Bridge was being built he went down into one of the caissons, and the sensation experienced was a very pleasant one. He suffered no evil consequence afterward.

Dr. Roosevelt inquired whether divers suffered in the same way, and Dr. Smith replied in the affirmative.

Dr. Robinson wished to know what induced men to work in these dangerous occupations. Did they know of the danger?

Dr. Smith said they knew the danger. The chief attraction was good pay for short hours. Being asked whether he had ever been in caissons, and whether he had experienced any trouble, he said he had frequently been in them, but had not stayed long at a time and had never been affected. He added that in general one or two atmospheres endured for four hours was equal to four atmospheres endured for two hours.

The President, Dr. Peabody, said that he had seen what was called caisson disease in a diver who had never been in a caisson. His symptoms were confined to the lower extremities and the bladder. The patient came under Dr. Peabody's observation in the second week, when the chief symptoms were paralysis of the bladder and loss of motion in the lower extremities, the pain having about disappeared. He remained under treatment two weeks, improved materially, and then disappeared. The patient told him that all divers were hard drinkers, and that mild attacks of his disease were very common among them. They would become doubled up with severe abdominal pains, which would disappear after they had swallowed two or three glasses of whiskey. The paralytic symptoms, however, were not very common, at least not as common as abdominal symptoms.

Dr. Peabody thought it was a great pity that there had been so few well-reported autopsies in the caisson disease. He knew of but two, in both of which lesions of distinct myelitis were found in the cord. He believed the theory of the disease which had been most accepted was that of Paul Baer, namely, the escape of nitrogen from the blood. He supposed the reason why the spinal cord suffered most was that its symptoms were more striking.

Dr. Smith made some closing remarks. He said that two autopsies at the Presbyterian Hospital revealed small but distinct air-bubbles under the epithelium of the mesentery, over quite an area. Men who began work at the time when a tunnel was first started and followed it up as it progressed, became accustomed to the increased pressure and were much less likely to be affected by the caisson disease than those who began at a later period, when the pressure was already great. This had been observed during the building of the Brooklyn Bridge and other occasions. One of the men who were sacrificed during the building of the bridge succumbed the first time he entered the shaft.

Regarding the question of the escape of air into the tissues, he had made some experiments which went to show that the amount of air which was taken up was very small, and that under ordinary conditions there was ample time during exit from the tunnel for the escape of all that air through the lungs. Paul Baer himself had found that it was necessary to apply a pressure of five atmospheres during a period of three months before he got the phenomenon referred to by Dr. Peabody, bubbles of air in the blood. Such condition never existed in any cases of the caisson disease. Then, too, it was difficult to conceive how persons could become inured to the presence of air-bubbles in the blood. It was a condition to which the system could not, by any amount of gradation, accommodate itself; whereas, accepting the theory which he had offered, one could readily understand that the blood-vessels could become accustomed to the varying degrees of pressure, when this was not so great at any one time as to destroy life or cause paralytic symptoms.

Concerning the Custom of Abusing the "Abuse of Medical Charity."—Dr. J. West Roosevelt read a brief paper bearing this title (see page 134).

Dr. Andrew H. Smith said it seemed to him that if we came down to the foundation of the matter, it would be found that the profession was to blame for the abuse of medical charity, and if they would turn around and abuse their own work they were doubly at fault. It was a common thing, he thought, to see the same individual occupying opposite positions in this matter at different periods in his life. The young man who was very anxious to get dispensary opportunities was not inclined to regard the abuse as very serious. When he got through the pupilage and began to look around for practice, he then found that it had been a very serious abuse. Until somebody could find some way to procure clinical material in sufficient quantity to meet all the demands of the profession, he did not believe that the profession itself would succeed in curing the abuse of medical charity. Of course many people received the benefits of medical charity who did not deserve them; but back of all that was the constant demand for clinical material, so that those very people were dragged, as it were, into dispensaries for the very purpose of supplying such clinical material. He would be glad if Dr. Roosevelt could suggest some way of reconciling these two opposing forces.

Against more Dispensaries.—Dr. Roosevelt thought there was one thing which could be done in a practical way, and that was for the profession to place the whole of its influence against establishing any more dispensaries of any kind, with the exception, he might add, of hospitals for the incurable and for the infectious and contagious diseases. The stand-point from which we viewed this question varied not only with the individual, but at different times with the whole profession. At the present time men were lauding the benefits of clinical opportunities and the great good which resulted to the human race from such clinical opportunities. While the teaching institutions might be quite right in giving a certain class of patients the benefits of free consultation, when they might be able to pay more or less elsewhere, he thought it would be absolutely wrong for the ordinary dispensary, not connected with any teaching institution, to do the same thing. Still it was impossible for even teaching institutions to continue indefinitely giving the benefits of free medical advice to persons who were well able to pay.

Dr. Roosevelt did not know of any definition of what constituted a fit case for the dispensary. A number of points ought to be taken into consideration: The person's financial condition, family relations, nature of the disease, etc. For instance, if Mr. Smith, who out of his wages of three dollars a day had been able to lay up a little sum, should become sick with a disease which not only disabled, but might lay him up for an indefinite length of time, should we say that he should pay over his last cent to a neighboring physician, and be reduced to absolute pauperism before he was entitled to medical charity? There might be some in the same family receiving sufficient income to enable them to pay a physician, while other members being entirely dependent were proper subjects for free treatment. To sift the subjects worthy of charity from those who were unworthy because able to pay, was a difficult task. The provident system had been tried, but was foreordained to failure. To send persons around to investigate the living condition of those applying for treatment at dispensaries would require in New York an expenditure of about three hundred thousand dollars a year.

The speaker said he had no new suggestions to make, but wished the members to remember that it was doing the profession harm to continue an indiscriminate abuse of the subject, especially in the indirect way in which it had been done. We heard laymen speak of the jealousy and impracticability of doctors, and there was some foundation for the statement as long as doctors attacked questions in what might be termed a murderous way, instead of being reasonable and consistent.

New Charities may be Justified.—Dr. Virgil P. Gibney doubted whether all physicians could accept Dr. Roosevelt's suggestion, and turn their faces absolutely and positively against the founding of new charities or new dispensaries. It should be remembered that all existing institutions had been new at one time, and all new institutions had to do a certain amount of advertising in order to get established. They had to seek the money of the public with which such institutions were supported, and until they got well under way it was but natural that they should try to make a good showing in the numbers treated by rejecting none who sought relief. It ought also to be remembered that old institutions sometimes got into routine ways, and it was good for the public, especially the dispensary public, to stir up better effort by founding new institutions. With regard to present institutions, one should not forget that the positions on the staff were all filled, and, in most cases, a large number were on the waiting list, so that when a man died or dropped out by resignation it required an immense amount of wire-pulling to get his place. Dr. Roosevelt had said that the dispensaries and hospitals were already so crowded that the doctors could not do justice to the work. Why, then, not found more dispensaries and hospitals, and let the men who were waiting have a chance to do justice to the work and the patients?

Dr. Roosevelt thought it would be better for existing dispensaries and institutions to be enlarged, and more men be added to the working staff. Let those who had money to spend on medical charity spend it upon institutions already established, and thereby save them perhaps forty per cent. of their present expenses. Regarding the young men who had no hospital or dispensary position, we had to deal with a larger question than the wants of one person or of a number of persons.

Dr. Samuel Sexton did not think Dr. Gibney's question had been fully answered. There were certainly as many men out of dispensaries as in them, and they would like to get to work, yet there was at present no possible opportunity. He saw no reason why they should not get together, establish an institution, and push themselves forward as others had done before. No one in a hospital would get out and let others in. Then let the others make a place for themselves.

Dr. Roosevelt thought we should not approve of a method because it might make things easy for some individuals. He objected to the public doing anything in the name of charity when it was for the benefit of some young men.

Dr. Sexton said he thought much was done in the name of charity which was nothing but a matter of business.

Dr. Peabody thought Dr. Roosevelt's proposition was a true one, viz., that it was no function of a dispensary to do anything except to give gratuitous medical aid to people who could not afford to pay for it. It had no right to establish itself as a protector of doctors; if incidentally it taught doctors, that was another matter, but it was not the function of a dispensary to protect doctors or do anything except treat the sick poor. Personally, however, he thought it was about impossible to say who were the poor among those who came to one and said they were poor. After all, one had to take their word: no amount of investigation would solve the problem.

Dr. W. G. Thompson thought the question not a very clear one. By increasing institutions we were actually pauperizing the people. He did not know that we could at present do better than follow the suggestions of persons working among the poor. They had better opportunities than others of judging of the facts in the case. Most of them, he believed, had confirmed the general impression that medical charity had been much overdone.

Dr. Beverley Robinson thought dispensaries had done not a little harm by leading poor people to exaggerate the importance of their ailments. This came through the subdivision of labor into specialties, so that if a patient had disease of the throat he was referred to one doctor, if

of the abdomen to another, and so on. Speaking with the experience of one who had treated a certain class, he was convinced that some patients had wasted time at the dispensary which they, as poor people, could ill afford to lose. The doctor's special efforts to cure them was probably the cause of their exaggerating their ills and of placing undue reliance upon the action of drugs. The same evil prevailed in no small degree in private practice, well-to do people being compelled to lose much time visiting several specialists for different affections, when a broadly educated general practitioner could meet all the indications in the case.

OUR LONDON LETTER.

(From Our Special Correspondent.)

VITAL STATISTICS OF THE NAVY—DANGEROUS TRADES AND SANITARY QUESTIONS IN PARLIAMENT—MEDICAL SOCIETY OF LONDON—PERIPHERAL NEURITIS WITH ATROPHY—THYROID TREATMENT IN SKIN DISEASES—OBSTETRICAL SOCIETY—ALBUMINURIA IN PREGNANCY—RETINITIS—ECLAMPSIA AND OTHER FITS—INFLUENZA IN LONDON.

London, January 13, 1894.

The Report of the Director-General of the Medical Department of the Navy has been presented to Parliament. It is a volume of considerable interest to those who appreciate statistics, though to others it may prove rather heavy reading, for 100 pages out of the 208 consist of tabular matter. There are in addition maps illustrating various points set forth in the report. The returns as to the total force, show that the health of the Navy for the year may be regarded as satisfactory. The vital statistics of our Navy and naval hospitals, and stations at home and abroad, are in this report analyzed and presented in a condensed form.

In the House of Commons the Home Secretary has announced his intention of introducing a bill next session, dealing with long hours of work in dangerous trades, such as alkali and other chemical works. This is really the result of a committee of the House on the subject. The Government have also decided to reduce the working-day at Woolwich Arsenal to eight hours. In reference to some other departments, inquiries are said to be going on, which no doubt means that we may expect the same boon to be extended to all workmen under Government. Some are declaring that this is only a move to secure the votes of workingmen at the next election; but political gratitude to a party is rather likely to follow the example of the greedy little boy, who illustrated his by "asking for more."

Questions as to female factory inspectors, unwholesome houses in London, vaccination, lodging-houses, and contagious diseases, have also come before the House. So has the rather remarkable discovery of a quantity of human bones, estimated at about a ton, and conjectured to be the remains of persons who perished in the great plague and were hastily buried during the terror that prevailed. It was presumed, said the Home Secretary, that those who superintended the excavations would see that the remains were decently interred. At the Medical Society of London, on Monday last (January 8th) a paper was read by Mr. William Anderson, relating the case of a lad, aged fifteen, who, after a day's skating, was very much done up, and returned home. A day or two later he developed swelling and pain in the joints of the lower limbs, with a high temperature and abundant sweats. His medical attendant regarded it as rheumatic fever; but the constitutional disturbance did not subside for ten weeks, when all the joints of the lower limbs were fixed and rigid. In endeavoring to procure some mobility of the knee the stretched and inelastic skin broke down, leaving a very nasty wound. Later an abscess formed in the neighborhood of the hips, and this was followed by atrophic lesions affecting the skin and certain groups of muscles in the lower limbs. At St. Thomas's Hospital he was put under a course of massage, and in some months recovered so far as to be able to get about by the aid of a stick. He was shown at the meeting, to illustrate what is now described as "A case of Peripheral Neuritis followed by Multiple Anchylosis and Atrophic Manifestations."

Mr. Lockwood thought the symptoms were compatible with the disease having been due to some infective agent, and he experienced a difficulty in thinking that any other cause would account for such extensive suppuration as this lad had undergone. Peripheral neuritis occurs in association with various forms of septic infection, and he asked whether there had been any effusion into the joints, and also whether any albumin had been discovered in the urine, as such was usually the case in septic infection.

Mr. Anderson explained that he had dismissed the possibility of the case being due to infection, as the abscess in the thigh did not come on until ten weeks after the onset of the symptoms; the traumatic condition was limited to one side, and the muscular and cutaneous lesions did not appear until after that date. There had been effusion into the joints at the beginning, but there was none on the lad's admission to the hospital. No albumin had ever been detected in the urine subsequent to his admission, and nothing was known of the condition previously in this respect.

Dr. Abraham then gave the result of some ninety cases of various skin diseases, in which he had tried the effects of the administration of thyroid extract. Of this number there were sixty-five cases of psoriasis, the remainder being made up of cases of lichen planus, lupus, leprosy, eczema, etc. Unfortunately the value of his results is impaired by the fact that, in most of the cases, the patients were making use of some other treatment at the same time; but Dr. Abraham arrived at the following conclusions: 1. That the ingestion of thyroid extract has no constant effect in psoriasis and other skin affections. 2. That the results are often negative, and in a few instances the disease is even aggravated. 3. That in a small number a markedly curative effect was produced. 4. That there are no indications of the class of cases likely to be benefited thereby. 5. That severe constitutional effects are often produced. 6. That age and sex do not influence the effects of treatment, successful or otherwise. Mr. W. Anderson referred to a typical and severe case of eczema in a man, aged thirty-five, of thirty years' standing, in which not only did no good result follow, but his last condition was worse than the first, though when the external application of tarry preparations was substituted the patient promptly and rapidly improved.

Dr. Hingston Fox pointed out that the gland itself varies considerably, not only in size, but probably also in physiological activity. Moreover, the gland undergoes periodical changes in woman, and probably also in animals; and as we know nothing of such changes, we must expect discrepancies of observation until the active principle of the thyroid is separated.

The serious significance of albuminuria during pregnancy is a source of anxiety to many practitioners. It is generally accepted that some cases may do well, although it is difficult to distinguish them from others which are of the gravest import. The prognosis is, therefore, fraught with uncertainty and apprehension.

Dr. Herman, President of the Obstetrical Society, related six more cases at the last meeting, and compared them with eleven others which he had communicated on former occasions. He said there were evidently two forms of renal disease to which pregnant women are liable. One is very acute, with few if any premonitory symptoms, diminished quantity of urine, and that small quantity deficient in urea, but containing enough albumin to solidify on boiling. The fits in such cases recur rapidly, and unless the excretion of urea is restored, death soon ensues; but if the secretion of urine increases and contains more urea, the fits may cease and the patient

recover. The other form is chronic, the premonitory symptoms occupying weeks or months. There is increased secretion of urine, with much loss of albumin, but not so much in proportion to the liquid as in the acute form. There is diminution of urea, but not to the extent found in acute cases. Delivery is followed by increased elimination, and when this is considerable the albumin diminishes and the patient gets well; but if it is only slight, the case becomes one of chronic Bright's disease. The most grave symptom is retinitis. In the acute disease with eclampsia, and in the chronic cases when there is intra-abdominal pressure, much of the albumin is paraglobulin. When it is chiefly serum-albumin, the patients either die or pass into chronic Bright's disease. Dr. A. Routh differed from the author as to paraglobulin, which he found in the lighter rather than the graver cases. Dr. Duncan referred to two cases in which there was albuminuric retinitis, promptly relieved on emptying the uterus, and he insisted that this was the proper treatment as soon as retinitis set in. Dr. Horrocks could not recollect any case of recovery from albuminuric retinitis, and said that the fits that occurred during pregnancy or labor, apart from albuminuria, were of a different kind, and usually were amenable to bromides. In his reply, Dr. Herman commented on the great differences observed in the renal affections during pregnancy from those in other circumstances. None determine fits within so short a time from the onset as those associated with pregnancy, and the rapidity with which the gravest symptoms subside on emptying the uterus is most remarkable. After death from puerperal eclampsia, marked renal mischief is often conspicuously absent. He not only agreed with Dr. Duncan that labor should be induced as soon as the retinitis set in, but would even induce it in every case of severe albuminuria, in order to lessen the liability to chronic kidney disease. He held that the term eclampsia ought to be used only for albuminuric cases; others might be distinguished as "fits without albuminuria."

Influenza is declining rather rapidly. Last week the deaths registered, in London, from this disease were 87, as against 164, 147, and 108 for the three weeks preceding. The disease this time is of a milder type, but it shows a tendency to attack the larynx and nares, and some cases have simulated whooping-cough from the paroxysms of cough arising from the irritation of the larynx. In some of the cases, too, the onset is remarkably sudden. I have met with some who declare they felt seized in a moment, as, for instance, in crossing a street, with a severe feeling of illness, when the instant before they felt in perfect health.

TURKEY AND PTOMAÏNE.

To the Editor of the Medical Record.

Sir: In your edition of January 6, 1894, I find an article by Dr. H. H. Seelye, of Amherst, Mass., in which he describes a case that occurred in his practice; in this case fifteen people that had partaken of turkey were taken sick, under symptoms which led the doctor to believe that they were suffering from atropia poisoning.

I feel it my duty to draw the attention of your readers and the author to the fact that, far from being a unique case, it was a mistaken diagnosis; the patients did not suffer from atropia poisoning, but from ptomaïne poisoning.

To prove my statement I may be permitted to quote, Berger: "Maladies des Yeux dans leurs rapports avec la pathologie générale;" Paris, 1892, page 392. "Déjà, en 1869, Zulzer et Sonnenstein ont montré que les réactions dues aux produits toxiques de la putréfaction sont analogues à celles de l'atropine; l'empoisonnement qu'ils déterminent a pour résultat de dilater la pupille et d'accélérer le pouls. . . . Des troubles oculaires se manifestent généralement de très bonne heure dans l'empoisonnement par les ptomaïnes: on voit survenir la dilatation des pupilles et la paralysie du muscle de l'accommodation. . . . On prétend aussi avoir observé des troubles oculaires produits par une action locale des ptomaïnes."

Translation:

"Already in 1869 Zulzer and Sonnenstein have proven that the symptoms caused by toxic products of putrefaction are similar to those caused by atropine; the poisoning which they cause effects a dilatation of the pupil and quickens the pulse. . . . In ptomaïne poisoning, eye troubles show themselves generally very soon; dilatation of the pupil and paralysis of accommodation is noticed. . . . It has also been claimed that eye troubles have been produced by a local action of the ptomaïnes."

I could quote other authors, as Knies, Bouchard, etc., but I think it unnecessary.

It is a well-known fact that ptomaïne poisoning is very often caused by sausage-meat, cheese, fish or vanilla ice-cream, even if these substances are apparently fresh.

A. W. Herzog, M.D.

NEW AND RAPID METHOD OF ANÆSTHESIA.

To the Editor of the Medical Record.

Sir: In submitting my article, on the above title, to you for publication in the Medical Record of November 18, 1893, in answer to Dr. Magill's article of October 21, 1893, I did not think I should be obliged to ask your indulgence for a second communication on the same subject; but as my former one appears to have failed in its mission, viz., "Honor to whom honor is due," and as I am challenged to corroborate facts therein cited, I will endeavor to be as brief as possible and, as well, thorough.

In Dr. Magill's second paper in the Medical Record of January 13, 1894, the attention of the reader is directed wholly and entirely to the use of chloroform after bromide of ethyl, and no mention is made of ether; and, if I understand aright, his claim of priority applies only to the use of chloroform following bromide of ethyl. In Dr. Magill's first communication to the Medical Record of October 21, 1893, I find it distinctly stated "that the complete anæsthesia is immediate, instead of resultant of a period often long, which is necessary in the process of chloroform anæsthesia [and more so in case of employment of ether]" the bracketed portion being added by Dr. Magill. I also find, "advantage 2. Doing away with all violent agitation on the part of the patient, so common when chloroform or *ether* alone is used" (italics my own).

From the fact that ethylization followed by etherization is mentioned in Dr. Magill's first article, and originality in the method of administration was claimed by him, and the entire matter totally ignored by him in his second article, I conclude either that, by my reference to the *Medical and Surgical Reporter* of August 7, 1880, I demonstrated satisfactorily to him that his claim of priority was unfounded (and if so why did he not admit it in his last article?); or that I misunderstood his first article, and that it was misleading, the two sentences above quoted will show.

Dr. Magill questions that Dr. H. Augustus Wilson, in the article published in the *Medical and Surgical Reporter* of August 7, 1880, in any way mentions the combined process of anæsthesia by ethyl bromide and chloroform. The process is not mentioned in this article, but the process of anæsthesia by ethyl bromide and ether is mentioned, and so far as I have been able to determine, Dr. Wilson's article is the earliest published reference to this method; hence the "honor" belongs to him.

I referred also to Dr. E. E. Montgomery's report of its use in this capacity, giving, however, no journalistic reference. In the *Therapeutic Gazette* of June 15, 1892, Dr. Montgomery published an article on "Bromide of Ethyl," and on page 366 I find the following: "Chis-

holm and Prince have administered it in several thousand patients, the former, etc., and the latter preceding anæsthesia for major operations by the use of this drug (bromide of ethyl), and thus recommends it for its value in obviating the unpleasant stage of excitement upon the use of the other and more permanent anæsthetics." One might ask what is meant by "the other and more permanent anæsthetics," for anæsthesia has been accomplished by ether alone; chloroform alone; alcohol, chloroform, and ether; chloroform and ether; nitrite of amyl, chloroform, and ether; hypodermatic injection of morphia and atropia preceding ether; nitrous oxide; nitrous oxide and ether; bromide of ethyl; bromide of ethyl and ether; and bromide of ethyl and chloroform. In the October, 1883, number of the St. Louis *Medical and Surgical Journal*, Dr. A. E. Prince (referred to in Dr. Montgomery's article) published "Observations on the Use of Bromide of Ethyl as an Anæsthetic for Short Operations, and as a Precursor to the Administration of Ether," and in it we find the kind of anæsthetics to which Dr. Montgomery refers. I quote the following: "The aim of the following remarks will be, first, to place it, etc.; second, to suggest a new function which has been found of value only secondary to the above, viz., A Precursor to the Use of Chloroform and Ether."

This article is "illustrated by a brief of the first 50 cases" in which the combined or single administration was employed by Dr. Prince. In this "brief," I find that chloroform alone was administered after ethylization in cases 23, 28, 29, 30, 38, 39, 43, 46, 47, and chloroform and ether after ethylization in cases 22, 40, 49.

I have not sought for any further references to the subject, so do not know if there are any; but this proves conclusively that Dr. Magill's first experiments, August, 1892, were antedated by at least thirteen years in the publication of the administration of bromide of ethyl followed by ether, and by about nine years (February 7, 1883, being the date when first used by Dr. Prince) in the publication of the combined method of ethyl and chloroform. Truly, Dr. Magill's fears, expressed in his last article, viz., that I am led to the conclusion that his "priority" is "pretended," become realities, and the attention of the profession is only redirected to a method formerly used quite extensively. This may, however, be the means of reviving this use of the drug among surgeons, and if so, Dr. Magill will have accomplished considerable, and his labors in this field will still be rewarded.

Respectfully,

J. Torrance Rugh, M.D.

1431 Walnut Street, Philadelphia, Pa.

VICTORY FOR THE MEDICAL BOARD OF THE NEW YORK INFANT ASYLUM.

To the Editor of the Medical Record.

Sir: I hope you will allow me to express my thanks and gratification at the position you have taken in regard to the New York Infant Asylum and its Managers. As one of the members of the ex-Medical Board, I can assure you that you have done no more than justice to the medical gentlemen who once worked so faithfully for the Institution. There is no doubt that if even a modicum of courtesy and tact had been exercised toward the Board no trouble would have ensued. The final cause of our resigning was, however, as you have stated, not so much what had been done in the past, but rather the direct refusal of the President of the Managerial Board to allow us in the future any voice in nominating candidates to sit with us on the Medical Board.

It is gratifying now to find that our resignation as a body has accomplished precisely the object we desired. For Dr. Nicoll in his letter to the Medical Record describing the radical changes which the organization of the Asylum had undergone, was not quite candid enough to add that the new Medical Board has been granted the right of nomination.

Apart from this personal vindication, it seems unquestionable that the Managing Board has been stimulated to a keener sense of its responsibilities, and there is no doubt that the Asylum will be greatly benefited through the act of the late Medical Board. I believe that the profession as a whole will cordially unite with the Medical Record in sympathy and support of the gentlemen who, like Dr. Holt, resigned, but who, unlike him, did not refrain from defending their act and so did not get reappointed, Yours very truly,

X.,

An Ex-Member.

Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

ELEVENTH INTERNATIONAL MEDICAL CONGRESS, TO BE HELD AT ROME.

Practical Hints and Suggestions for Intending Visitors.

Those who are familiar with transatlantic voyages and European pilgrimages require no instructions other than those which relate specially to the affairs of the Congress itself. But there are doubtless many who will go abroad for the first time on the occasion of the Eleventh International Medical Congress. It is for the information and guidance of this class of visitors that the following suggestions are made. The Medical Record has recently sent a representative over the country, and the hints we are about to give are based on personal experience.

Young children under no circumstances should accompany medical parties on this occasion.

Expense of Trip.—As to the probable expense of the trip to Rome it is impossible accurately to compute it. The principal steamship lines and European railroads offer reduced rates. Hotel charges in Rome will also be subject to special conditions, arranged by the Local Congressional Committees. An approximate estimate for one person's living expenses, including cab hire, gratuities, etc., is from six to ten dollars per day. The most rigid economy will not enable one to live, with ordinary comfort, at less than $5 per day. In going to the poorer hotels one exposes one's self to impositions that in the end make the best hotels the cheapest. In Italy everybody bargains, and even hotel-keepers will often take less than they ask. Make your arrangements by the day, and if not suited take a cab and drive from hotel to hotel, until your tastes and purse are equally suited. Never rely on the local guides, as they always get a commission which comes out of your pocket. Do not wait before asking for your bill till a few moments before your departure. If in doubt as to prices, ask for a daily account and pay as you go along. If you have decided to remain several weeks in one town, then a weekly *pension* rate is decidedly cheaper. Do not develop into a chronic kicker, even if you feel that you have been repeatedly imposed upon.

It will mar your enjoyment of Italy if you make a point of never being swindled or cheated. Don't insist on an American breakfast in out-of the-way places. The French and Italian breakfast consists of coffee and rolls. Eggs are, however, permissible.

Passports.—These are not now an absolute necessity for travellers in Europe, except in Russia and Turkey. Vexatious delays may occur, however, when they will be found useful. It is therefore best that all persons going abroad should carry them. On application direct to the Hon. Walter Q. Gresham, Secretary of State, Washington, D.C , blank forms of application will be returned, which are to be filled up and sent back to Washington, promptly, on receipt of which the State Department will return the desired passport. The amount of the trifling fee to accompany the application is stated on it.

Baggage.—The least one can travel with comfortably will be found the most satisfactory. On the voyage there will be needed, besides the suit of clothes one is wearing at the time of starting, a heavy overcoat and a thick shawl or a warm rug. If the voyage is to England, Germany, or France, winter clothing will be required at this season of the year all the way across the ocean. If the Mediterranean route be selected the temperature will rise after crossing the Gulf Stream, as the course is somewhat to the southward, but it is safer to change for thinner underwear than to leave off the heavy outside clothes. Do not omit to carry a dress suit. One steamer trunk and a few hand-bags or shawl-robes can be made to hold all that is necessary, and these can all be taken into the state room of the steamer. It is necessary that the trunk should be of the kind usually termed steamer trunks, or it may be so large as not to go under the berth, in which case it cannot conveniently be carried in the state room. The space between the bottom of the berth and the floor of the state-room usually measures about thirteen inches. Every piece of baggage should have a tag upon it, stating the number of the state-room on the steamer, and that it is to go into the room. If too large it will have to go into the hold of the vessel. The steamship companies supply these tags when passage is booked.

Money.—On arrival in New York purchase a letter of credit for such an amount as the expense of the trip may have been estimated at, and as expenses always exceed estimates, add one-third to the amount. It is not lost if not used. This should be obtained of some first-class banker, such as Brown Bros. & Co., or Drexel, Morgan & Co. Letters of credit issued by Thomas Cook & Son are also perfectly good.

The coin used in France, Italy, and Switzerland is the *franc* (1 franc = 100 centimes) = 9½ pence English and 19 cents American money. The franc is called *lira* or *franco* in Italy, and contains 100 *centesimi*. The legal coin of Germany is the *mark* (1 mark = 100 pfennige) = 1 shilling English and 24 cents American money. Austria has the *florin* or *gulden* (1 fl. = kreutzers) = 2 shillings English, or 49 cents.

If it is proposed to land in England, it will be best to purchase $10 or $20 worth of English gold and silver in New York. If the landing is to be made at Hamburg, get the same amount in German gold and silver. If in Havre or Antwerp, then the same in French gold and silver. If the voyage is to be direct to Genoa, buy the same of Italian money. In any event it is better not to carry any American money in one's pockets at all, as it will cause considerable trouble to exchange it on the other side or with the purser of the steamer, who is always ready to accommodate travellers in this way to his own profit.

Guide Books.—It will be found quite a help to buy Baedeker's or Cook's Guide to France and Northern, Central, and Southern Italy, and read them on the voyage over. These books are very practical, and any recommendations as to routes, hotels, etc., may be relied upon. In this connection it may not be amiss to say that if any American needs any assistance at any of the principal railroad stations on the Continent, if he will inquire for Thomas Cook & Son's representative he will find courteous and valuable assistance. Cook's railway tickets are the most convenient things one can travel on anywhere in Europe. They have offices in all the large cities, and are often friends indeed to the inexperienced traveller.

Steamship Lines.—There are a large number of lines regularly crossing between New York and various ports on the other side. Of these the most direct and convenient for those anxious to attend the sessions of the Congress is the German Mediterranean service, composed of the amalgamated lines of the North German Lloyd S. S. Co. (offices at No. 2 Bowling Green, New York City), and the Hamburg-American Packet Co. (offices at 37 Broadway, New York City). The Mediterranean Lines send the Fulda on March 3d, the Columbia on March 10th, and the Kaiser Wilhelm II., on March 17th. Single berth in state-room, first cabin, on the Fulda, from $70 upward; on Columbia, $75 upward, and on the Kaiser Wilhelm II., from $90 upward.

These companies inform us that delegates visiting the International Congress will be granted a reduction of twenty-five per cent. on the outward passage on any of their steamers, and ten per cent. on the return passage, if it is decided to return home by the same line. The vessels and service are first-class in every particular. Passengers by these steamers have an opportunity of seeing the Azores, Gibraltar, and Naples *en route* to Genoa.

Many will doubtless wish to go *via* England and across the Continent, stopping by the way at some of the noted cities through which they will pass. For such the splendid stanch steamers of the American Line to Southampton (offices in New York City, 6 Bowling Green) are decidedly the best. The Chester will sail March 10th, fare from $60 per berth upward, and the magnificent New York on March 17th. This latter steamer is one of the finest, most stanch and fleetest of all the superb modern steamships crossing the Atlantic. The White Star Line (office, 29 Broadway, New York City) send the Teutonic, March 7th, and the Britannic, March 14th, to Liverpool, England. Tickets from $60 upward. The Cunard Line (offices at No. 4 Bowling Green, New York City), dispatch the Aurania, March 3d, the Campania, March 10th, and the Umbria, March 17th. Passage on the Aurania and Umbria, $60 to $125 and upward, on the Campania, $75 and upward. Passengers are landed in Liverpool. The French Line (offices at 3 Bowling Green, New York City) have La Bourgogne, sailing on March 3d, La Gascogne on March 10th, and La Normandie, on March 17th. Tickets, $80 per berth and upward. There is still another route, which has advantages of its own, namely, the Red Star Line (New York offices, 6 Bowling Green), the Friesland, a new boat, stanch and luxurious, sails for Antwerp, March 14th.

On application to any of these offices, any information desired concerning any of these steamers, with deck plans, showing numbers and locations of the state-rooms will be promptly mailed. It is advisable to secure berths early.

Those who go by way of England will find it most agreeable to cross the English Channel from Dover to Calais. The railway trip from London to Dover takes about two hours. Another way of reaching the continent is from Folkestone to Boulogne-sur-Mer. Boats cross the Channel twice a day in two hours. Railway from London to Folkestone, three hours. From Calais proceed at once to Paris, and thence via Lyons, Marseilles, and the Riviera to Rome, or by way of the Mont Cenis Tunnel and Turin to Rome. On the Mont Cenis line the trains are equipped with sleeping-cars. First-class fare $40, and second-class fare about $28. Sleeper from Paris to Rome will cost $10. If the delegate arrives in Liverpool, his railroad journey by the same route as just described will cost, first class, $56, second class, $38.20. Sleeping-car as before. Delegates going direct to Genoa, go from there to Rome by rail in eleven hours. First class tickets, $12.20, second class, $8.55.

About the Voyage.—While it sometimes happens that the steamers are still at their wharves after the hour advertised for sailing, this is, in these days, a rare thing, and on no account should one fail to be on hand half an hour before the time advertised. Porters belonging to the ship will carry baggage from the wharf and place it properly, under the passenger's supervision, in the state-room for which it is tagged. It is necessary to make sure that this is correctly done. No fee is expected. While the steamer is fast to the wharf, the state-room on no account should be left with the baggage in it without being locked. After the lines are cast off this is no longer necessary during the voyage. As soon as possible after leaving the wharf it is advisable to see the steward and arrange for a place at the table during meals. If one is likely to be ill during the voyage, a seat on the outside of the table and as near to the door as possible is desirable. All the waiters on the English and German lines are called stewards, and garçon on the French line. The man who takes care of your state-room is also a steward. So also is the man who has charge of the comfort of the passengers on deck, and we thus have table stewards, cabin stewards, and deck stewards. The deck steward is the man who has charge of the blacking of shoes. No fees are expected until just before landing on the other side, when the steward who looks after the state-room will expect a fee of about $2.50, the one who waits on the table the same, and the deck steward, if he has simply attended to blacking shoes, about 50c., or from that upward to the same as the others, if the passenger has needed his service much during the voyage. If the smoking-room has been much frequented, the man in charge of it will be looking around for his tip of about 50c. This matter of fees is one which will not impress an American very favorably, but one who expects to travel with any comfort on the other side will be obliged to follow the custom, and it will be found most satisfactory to speedily fall in with it. Physicians are just as liable to become seasick as other mortals, so that it will be just as well not to experiment on one's self or one's fellow-sufferers with the latest remedy for mal-de-mer. It is quite possible that the voyage across may be made without any decidedly uncomfortable feelings, whereas, on the return trip it might be quite the reverse. Most sea-voyagers find it advisable when beginning to feel uncomfortable from the motion of the vessel, to give up and pay tribute over the side of the vessel at once. It not unfrequently happens that this early emptying of the stomach gives some relief, especially when it comes on immediately after rising in the morning. It is also far better to struggle up on deck into the fresh air, than to lie in bed in the confined atmosphere of the state-room. If one feels at any time that a few crackers, or ginger-snaps, or a light lunch of some kind, or oranges, or apples would taste well, if the state-room steward is rung for, he will bring them to your room day or night. There is almost no limit to the amount passengers are given to eat, on all of the transatlantic steamers, but he will have to pay for anything he desires to drink other than water, tea, and coffee.

Custom House.—Inspection of baggage at any of the transatlantic ports, either British, French, or Italian, is far less disagreeable in experience than in the United States. Cigars, liquors, and silverware are about the only articles the officers inquire about. It is not advisable to carry more than one hundred cigars, nor these in sealed boxes. It is best that the boxes should be opened and some taken out before the customs authorities examine them. No more liquor of any kind than the contents of a single flask should be carried on shore. Porters in England who carry baggage from the wharf to a cab expect from six pence to a shilling sterling. In France from ten centimes to a franc. In Italy, from ten centesimi to half a franc.

Baggage in Europe.—The American system of checking baggage to destination by means of tags is not used in Europe. Every trunk and parcel is weighed before being passed, and a receipt is given with a number upon it which corresponds with the number on all the slips pasted on the trunks and bags to be delivered. Europeans generally carry an uncomfortable amount of hand-bags into the passenger compartments, to avoid the compulsory payment for the carrying of extra baggage, only about fifty pounds being carried free by the railroad companies. Indeed on many lines every pound is charged for. It may be stated, however, that their charge is very much less than is charged on the American lines for what is termed extra baggage, and unless the amount carried by a passenger is very large, it does not add very much to the expense of travelling. Travellers should always be sure that their baggage is carried on the same train with themselves, or vexatious delays are sure to occur. On arrival at destination, it should also be looked after in person. The railway employee who weighs your baggage is considered entitled to a very small fee in England (about four pence), and on the continent its equivalent. The man who puts it on the baggage car expects a small amount, six pence or one shilling. The man who takes your handbags, if you have more than you can carry yourself, which it is always best to avoid, should have the same. It takes a very short time for an experienced traveller to fall into the ways of the country he is visiting. It is quite unwise to be too lavish in these gratuities, for trifling as they may appear separately, they become a very considerable sum at the end of a tour. Travelling in Europe is dearer for an American than in his own country, and unless one knows the language and ways of the people, he has to submit to many petty depredations, with the best grace possible. But if he goes expecting more or less of this sort of thing he will be philosopher enough not to let it destroy his pleasure.

From London to Rome.—Tickets for Rome are purchasable in London. It is, however, just as well to buy them in Paris. Take your baggage with you. It is, of course, much cheaper to have it forwarded as freight. But the uncertainty regarding its fate and time of arrival outweigh the saving made. Unless pressed for time, stop at least one day in Paris. As to Parisian hotels, Americans prefer those on and near the *Rue de Rivoli*, or the *Place Vendôme*, and the commodious Grand Hotel, on the Boulevard des Italiens. The trip from Paris to Genoa is best accomplished by taking the Paris, Lyons, and Mediterranean Railroad, via the French Riviera.

Stop one day at Marseilles, and if not pressed for time, one day each at Cannes, Nice, Monte Carlo, Mentone, and San Remo. At Marseilles the best hotel is the *Grand Hotel du Louvre et de la Paix*. At Cannes, Nice, and Monte Carlo there are plenty of first-class hotels. At San Remo the West End and *Grand Hotel des Anglais* are the best.

Those who do not wish to break the trip at Paris, and to whom comfortable through travelling is an object, may remember that the Southeastern Company has made, in conjunction with the Continental companies, special arrangements to enable invalids to travel with speed and comfort from London to Cannes, Nice, Monte Carlo, and other places on the shores of the Mediterranean. They will be conveyed on Tuesdays, Thursdays, and Saturdays by the "club train" special service, which, leaving Charing-Cross at 3.15 P.M. daily, calling at Paris ("Nord" Station), and running on through to the Riviera, reaches Cannes the next day at 7.11 P.M., Nice at 7.46 P.M., Monte Carlo at 8.34 P.M., and Ventimille (Italy) at 9.7 P.M. The usual daily through mail services will also afford accommodation by *coupé-lit*, *toilette*, and *coupé-fauteuil* carriages through from Calais, running as they do in connection with the Dover and Calais steamers *Empress*, *Invicta*, *Victoria*, and *Calais-Douvres*.

For particulars on this subject travellers cannot do better than consult Messrs. T. Cook & Son, Ludgate Circus, Charing-Cross, and 33 Piccadilly, etc., who are always ready to afford every assistance in their power.

It is also well to remember that the "*rapide*," which leaves Paris for the Riviera at 7.15 every evening, is often

overcrowded. To get a seat it is advisable to be at the *Gare de Lyon* one hour before the train starts. Even then it may be necessary to circumvent some wily traveller who has filled up two corners of the compartment with his impedimenta, and unblushingly asserts that he is keeping a place for a friend. The expensive *train de luxe* service, which runs twice a week from Calais to the Riviera, is also generally very crowded at the beginning of the season. It is always best to book "berths" several days beforehand. Those who do not care to go to this additional expense will find an ordinary express more comfortable and less tiring than the popular 7.15 *rapide*, as there is very little difficulty in getting a separate first-class compartment. Toward the end of March, however, the tide of travel has set in northward, and hence visitors to the Congress may be subjected to very little crowding in these special trains.

The other route before referred to from Paris to Rome is via the Mont Cenis tunnel to Turin and Genoa. It is a much cheaper but more tedious and uncomfortable way of getting to Italy. It is necessary to change cars at least twice in going by this route. One also misses entirely the beautiful scenery of the Riviera.

Genoa.—The easiest and probably the most agreeable way to reach Rome is by way of the Hamburg-American line, and also by the German Mediterranean service of the North German Lloyd. The steamers of this new service are all first-class. The ocean route is a southern one. The steamers touch at Gibraltar, and passengers are landed on Italian soil.

A few words relative to Genoa, known as *La Superba*, will not be amiss here.

One cannot fail to be struck by the beauty of the harbor of Genoa, a semi-circular bay over four miles wide. On landing the first thing to do is to keep cool. There is always much bustle and confusion on account of the custom-house inspection of baggage. There is a contagion of unrest in the very air. The petty officials, however, are polite enough to those who patiently submit to the examination of their effects. Cigars and liquors are the articles most diligently searched for. Only about twenty cigars will be passed here. Nothing else is apt to give trouble. And the ordeal will be found far less trying than is commonly supposed, if only one is ready to be scrupulously polite to the small-fry inspectors.

The hotels of Genoa are all poor, and Americans are charged high rates. The Hôtel Isotta, in the *Via Roma*, is the largest and one of the best. The managers and waiters understand French and English.

Other hotels are the Grand Hôtel du Parc, *Via Ugo Foscolo*, and the Grand Hôtel de Gênes, near the *Teatro Carlo Felice*.

Do not be persuaded to visit the Campo Santo unless the weather is dry and fine. Confine your sight-seeing to the principal streets and palaces. You will see better paintings in most other Italian cities.

Those who wish to proceed at once to Rome can have their baggage booked through on the dock. It is more advisable, however, to spend at least one day and night at Genoa.

It may be well to remember that the porters (*facchino*, pronounce fakeno) are not always honest, and universally attempt petty extortions. A few cents is all they are entitled to for carrying hand-bags and parcels.

In most Italian towns, it is just as cheap to hire a cab to take you to the hotel as to get into an over-crowded hotel omnibus. Cab-drivers generally understand French, and often a few words of English. When in doubt about the fare, tell the concierge of the hotel to pay the bill.

Cab-hire is cheap in Genoa. The following is the official tariff:

	By day. Fr.	Ct.	By night. Fr.	Ct.
Per drive	1	00	1	50
Per hour	1	50	2	00
Each additional half-hour	0	75	1	00

American Consulate: Mr. Fletcher, *Via Assarotti*, 14.

Bankers: Granet, Brown & Co., *Via Garibaldi*, 7. For all information concerning telegraph, post office, omnibuses, street-cars, steamboats, railroads, time-tables, churches, theatres, drives, etc., apply to the concierge, or head-porter. This individual is pompous and condescending, but as he always knows English his superior attainments must be reckoned with.

From Genoa via Pisa to Rome.—Italian train service is poor. It is necessary to travel first-class. The average speed of the best trains rarely reaches thirty miles an hour. Even in the first-class compartments, the prodigious amount of hand baggage carried by passengers, makes travelling uncomfortable. When the station-master (*capostazione*) shouts out *partenza* (departure) the train moves slowly out. American hurry has no existence on Italian soil.

Be at the station forty minutes before time of departure. It takes time to buy a ticket, to see that you are not cheated, to have your baggage weighed, to see that it gets into the baggage van, to show your ticket to several officials, to make sure that you get on the right train, etc. Tickets are generally given up on leaving the station of your destination. The exit is marked *uscita*. But in going to Rome the conductor usually collects tickets on the train.

Be sure that you know, at least approximately, the weight of your baggage, or you will be rudely cheated. Carry no articles of value except on your person. Remember that one Kilo (*i.e.*, Kilogramme) is equal to about 2½ lbs. Bear in mind that Italian railroad employees are underpaid, and therefore driven to thievery. The *facchinos* (porters) are entitled to a tip of a few sous (big coppers). If you give them silver they will probably ask for more, on the assumption that you are a "greenhorn."

Don't enter a smoking compartment, "*pei fumatori*." The stench of Italian tobacco is intolerable to American nostrils. The right compartments are marked "*è vietato di fumare*."

Those who intend to make an extended Italian tour will save money by buying *viaggi circolari*, *i.e.*, circular tickets available for from thirty to sixty days.

They are supplied at all of Cook's agencies. The only drawback to the use of those tickets is that it is necessary at each fresh starting-point to have them stamped with the name of the next station at which the traveller intends to alight. The crowd around the single stamping-window is often so great that trains are sometimes missed. If the stamping is forgotten a heavy penalty in the shape of triple fare is exacted.

Pisa.—Those who have decided on a personal inspection of the famous leaning tower may stop over one day at this ancient city on the banks of the Arno. The town is one hundred and two miles distant from Genoa, and two hundred and seventeen miles from Rome. Express trains run to Rome in about eight hours. The hotels are all poor. The least poor are the Bretagne, the Grand Hotel, the Nettuno. At the Hotel Royal Victoria, English and American notions are understood, and the proprietors at least try to please.

Those who have some slight knowledge of Italian will do best to leave their baggage at the station, take a cab to the Cathedral, pay the cabby on alighting, spend a few hours inspecting the Cathedral, the Baptistery (*Battistero*), the *Campanile* (clock-tower or *leaning tower*), the *Campo Santo* or burial ground, and then drive back to the station in time for the next train to Florence or Rome.

Rome.—It is of course not yet known what arrangements will be made by the Local Italian Committee to facilitate the finding of proper hotel and private accommodations. Ordinarily it is necessary to order one's rooms beforehand (one to two weeks) if one expects to be properly provided for during the height of the Roman season. Foreigners of the average tourist kind flock to the Eternal City at the very time appointed for the meeting of the Congress.

On arriving at the railroad station there is generally a vexatious delay owing to baggage inspection by the city customs officers. Possibly this will be entirely done away with for members of the Congress. Have your card ready, showing that you are a doctor, and tell the inspector you are there for the *Congresso medico*.

It is not necessary to use the hotel omnibus, as an ordinary cab is quicker and not more expensive. But if you have large heavy trunks with you, then it is safer to take the omnibus. Most of the hotels send English-speaking porters to the station, so that one can manage to get along without a word of Italian.

Hotels.—The Roman hotels are, with few exceptions, not of a very high order of excellence. Do not allow yourself to be put in one in the old quarters of the town. The fleas alone will be unbearable there.

About the best hotel in Rome is the Bristol, in the *Piazza Barberini*. But it is a very small and very dear establishment. The Quirinal, under Swiss management, is a large and first-class hotel. It is often difficult to find accommodation there. Have rooms reserved by cable for a certain day, if you insist on stopping there. It is very popular with English-speaking people. Hotel Quirinale is the Italian name. It is located in the *Via Nazionale*. Other good hotels in the newer and healthy quarter (known as the Strangers' Quarter) are the Hotel Continental (*Via Cavour*); Hotel de Londres (*Piazza di Spagna*); the Roma (*Corso*); the Grand Hotel de Russie (near the *Piazzo del Popolo* and the Pincio Gardens); and the Hotel Royal Mazzeri (*Via Venti Settembre*).

Those who intend to make a more prolonged stay in Rome can find comfortable apartments in some of the numerous *pensions*. Many of these boarding-houses are managed by English ladies. Mrs. Shearman has an American establishment. For a stay of one week or less hotels are decidedly preferable. The Pension Tellenbach is one of the largest and most popular.

Cabs.—These conveyances are cheap in Rome, but the omnibuses are cheaper (ten to fifteen centimes). Do not attempt to save on this item, for if you fatigue yourself by much walking you will invite sickness. Do not fatigue yourself with sight-seeing in Rome. Always remember that your being an unacclimated stranger predisposes you to sickness. If you get a little feverish do not at once decide that you have caught the Roman fever. Do not eat overabundantly of new dishes. Always carry an overcoat with you. As you step out of sunshine into the shade you will probably experience a chilly sensation much more pronounced than you are accustomed to at home under similar circumstances. Do not force yourself to attend a section meeting if not thoroughly rested. And finally, do not attempt to learn the Italian language in one week. The people you are likely to meet generally understand plain English fairly well. Nevertheless you will probably acquire some experience in pantomime before leaving Italy for your home.

Supernumerary Breasts without Nipples.—Dr. Bué attended a woman in her third confinement, which occurred at term, in December, 1892. (*The British Medical Journal.*) Two days later a swelling developed in the anterior part of each axilla, especially on the right side. These swellings gave rise to pricking sensations. The patient noted, during the previous night, a feeling of tension in each axilla. The normal breasts were full of milk. The swelling on the right side was situated on the border of the pectoralis major and on the thoracic wall in the adjacent part of the axilla. It measured two and a quarter inches in diameter and over six in circumference, and was separated by a groove from the normal gland. Its centre lay four and a quarter inches from the right nipple. When the child was put to the right breast a distinct diminution in the size of the supernumerary gland was observed. Afterward it again enlarged. The skin over the extra gland was not reddened, but bore enlarged veins, as on the normal breast. There was no trace of any nipple, nor was the presence of dilated sebaceous ducts reported. The left supernumerary mamma lay in the same position as the right, but was much smaller. On the day after its appearance it vanished. Its fellow on the right side remained stationary all the time that the patient suckled.

An Antiseptic Varnish.—Berlioz has devised a covering for diseased skin and mucous membranes which he calls steresol. It is a mixture of gum lac with benzoin and Tolu balsam, the whole being dissolved in alcohol. The mixture is then impregnated with carbolic acid ten per cent. Essence of canella will mask the disagreeable odor of the phenol, while saccharine will remove the bitter taste of the varnish. The steresol can be applied to skin or mucous membranes by pencilling, having previously dried the membranes with hydrophile gauze. It will resist the action of the saliva when applied to the throat.

Behring's Serum.—Dr. Bruschke, of Berlin, pricked himself with the needle of a syringe with which he had just previously injected a mouse suffering from tetanus. The wound was immediately laid open and disinfected. Four days afterward (no symptoms having been noticed in the interval) a dose of Behring's serum was injected. On the second day after the injection symptoms appeared which may be understood as having been caused, either by some irritating matter in the serum, or as due to an attack of tetanus controlled and diminished in violence by the serum injection. The attack ended in complete recovery.—*Lancet.*

Treatment of Dyspepsia in Children.—Tordens, in a discussion of the therapeutics of infantile dyspepsia and the subsequent atonic condition of the bowels, makes four divisions of treatment: 1. Elimination of noxious elements by emesis, lavage (both rarely if ever called for), and catharsis. 2. Anti-fermentative medicines. Among these he includes the various combinations of pepsin, resorcin, salicylic acid. In cases of diarrhœa with markedly green stools, he recommends lactic acid in small doses. The following combination he also finds useful:

℞. Creosoti..... 2–4 drops.
Aquæ destil..... 35.00 gm.
Syr. altheæ..... 15.00 gm.
M. Sig.: A small spoonful every two hours.

3. Sedatives, warm baths, and light friction. For colicky pains a mixture of aqua chamomilla, subnitrate of bismuth, and syrup of anise often gives relief. 4. Tonics and stimulants for the subsequent atony, of great value are:

℞. Tinct. cascarillæ..... 10 drops.
Aquæ destil..... 50.00 gm.
Syrup..... 10.00 gm.

℞. Ext. cort. chinæ..... 0.25 gm.
Aquæ destil..... 50.00 gm.
Syr. aurante..... 10.00 gm.
M. Sig.: To be given in teaspoonful doses.

—*Boston Medical and Surgical Journal.*

Are There Pain Nerves and Pain Tracts?—At the conclusion of a paper read before the Neurological Society, Dr. C. L. Dana referred to the question of the existence or the non-existence of a pain-tract, and the advisability of our searching for it. Psychologists, he said, have come to the conclusion that pain is not a sensation, but a form of feeling; that it is not to be classed with the sensations of touch or temperature; that it does not have peripheral end-organs, and that there are no nerves in existence which on irritation produce pain alone; that there is no such thing as a pain tract; that in attempting to locate such a tract we are pursuing a will-o'-the-wisp. Dr. Dana said that after a very careful study of this question, he was inclined to the psychologists' view of the matter. If we claim that there is a special tract for pain, we can just as well claim that there is one for hunger and various other sensations. If there is a special tract for any of the common subjective sensations, there must be a special tract for all. If, he added, we could get rid of the idea that we must keep on hunting for a pain tract, it would save much exertion and many futile experiments on monkeys and men.

RECTAL INCONTINENCE AND ITS CURE BY TORSION.[1]

BY ARPAD G. GERSTER, M.D.,

NEW YORK.

RECTAL incontinence, though not as troublesome as urinary leakage, is yet a very disagreeable, and to some persons fatal, complaint, fatal to social and business possibilities, and depressing in every respect. As to the absolute degree of incontinence, this does not depend so much on the causal factors involving either the loss of the sphincter muscle itself, or the loss of its function merely. It depends more upon the process of intestinal activity, by which is influenced the state of cohesion of the fæces when they arrive at the breach.

We know that a properly regulated diet, with the digestive process slightly influenced by small doses of opium, will mostly suffice to produce that consolidation of fæces that is indispensable to the comfort of patients lacking sphincteric occlusion. But there are remarkable variations within the pale of normal health as to the activity of peristalsis, some men defecating once in two days, others twice or three times daily, the former ones producing hard formed scybala, while the latter's stools always appear to be semisolid or even semiliquid. Accordingly the management of the bowel of patients without a sphincter may be easy or difficult. In most cases it will be easy, as a rule, the exceptions being acute attacks of enteritis caused by transient influences. Occasionally, however, the question of rendering the patient comfortable and tolerably safe from mortifying surprises will be found immensely difficult. I refer here to a patient whose habit required evacuation of the bowel twice a day, the fæces being always semiliquid. He lost the use of his sphincter by a series of extensive operations performed by various surgeons for multiple fistulæ in ano. The anal aperture was an irregular, ghastly looking cavern, lined with bulging tabs of congested mucous membrane, from between which there oozed almost continually a quantity of semiliquid fæces. The man was unfit to do any kind of work involving contact with other people, and became a charge upon his relatives. No form of diet, no astringents, no opiate could retard peristaltic action in the manner observed in ordinary cases, where, solid fæces being produced, the fæcal column is easily retained for twenty-four hours to be then expelled, so as to render the patient safe for the space of another day. A number of plastic attempts were made to restore the mutilated sphincter to its function, but though the size of the aperture was materially reduced, the incontinence still remained. The cause of this was that the nerve-supply of the sphincter had been completely destroyed by extensive incisions and by displacement of the nerve-ends through cicatricial retraction. It was very difficult to identify the atrophied remnants of the mutilated sphincter, and hence the operation failed. The disheartened patient finally committed suicide.

Fortunately these cases are rare. Formerly they were incurable in the strictest sense of the word, as neither the function of the sphincter could be re-established, nor a satisfactory closure effected by plastic arrangements of skin and mucous membrane directed toward a narrowing of the anal orifice. We shall see later on that a mere narrowing of the breach, even if it attain the character of a stricture, is no safeguard against incontinence.

Having considered one factor of incontinence, that is the character of the digestive process influencing the cohesion of the fæces, let us now pass in review the other factor, that is the state of the sphincter muscle itself.

The sphincter may be in existence but useless, and this for various reasons. First of all is to be mentioned the more or less pronounced paralysis of the sphincter caused by spinal injuries and spinal maladies. Both of these forms may be temporary or permanent; but as they are usually accompanied by great sluggishness of the peristaltic motion, and for other obvious reasons, they rarely constitute a very great hardship and need not be dwelt upon any longer.

The second group of cases of sphincteric insufficiency is much more extended, and contains the numerous cases in which the sphincter itself, or both the sphincter and its nerve-supply, were severed by the surgeon's knife or by the elastic ligature, for the cure of multiple fistulæ in ano. Even one deep-going incision, involving the entire thickness of the sphincter, will produce a certain amount of retentive weakness, which, as I have seen, may cause considerable inconvenience to the patient. I recall the case of a very refined young woman, of agreeable presence, whose cheerful disposition changed into hypochondriasis and melancholia because she had to wear continually a bandage and pad. A complete division of the sphincter, posteriorly in the median line, was necessitated by a very extensive complete fistula. After the large wound had healed, the fæces could be easily retained, if solid: if semiliquid, however, they were apt to escape when she laughed or on slight exertion, causing her extreme anxiety and mortification. This laxity was easily relieved by exposure of the cut ends of the otherwise active sphincter, and their union by catgut suture. The line of sutures was protected by drawing down and stitching to the outer skin of the mucous lining of the gut.

Another illustrative case belonging to this group was that of H. W——, aged twenty, who, after an operation performed at Bellevue Hospital for fistula in ano, suffered from incontinence of fæces. The patient presented a widely patulous breach, with two wide and deep cicatrices, both in the median line, one anteriorly, the other posteriorly. The sphincter had been divided in two, and its semilunar two segments were far retracted. On irritation they both responded readily by a lively contraction, which, however, failed to close the anus. On May 6, 1893, at the German Hospital, both massive cicatrices were excised so far as to expose the cut ends of the two halves of the divided sphincter, which were then readily united by a double row of buried catgut sutures. After this the mucous membrane was raised for an inch and a half all around, and was drawn down and over the sutured sphincter. Prompt primary union followed, and the function of the sphincter was perfectly restored.

As long as the remaining segments of the sphincter show signs of irritability and contractility, measures at their union and the restoration of the muscular ring are justified, and will generally be more or less successful. But when the nerve supply has been irremediably damaged, and the divided nerve-ends and muscular segments were much displaced by cicatricial retraction, restoration of the sphincter becomes impossible. In addition, the rudiments of the muscle are so atrophied that they can hardly be recognized, and should it be possible to find and unite them, the lack of innervation will render the

[1] Read before the New York Surgical Society, January 24, 1894.

attempt at restoration of the function futile. The case related in the beginning of this paper may serve as a fair example of this form of the disorder.

To remedy this distressing condition, surgical ingenuity has devised a number of plastic operative measures, most of them directed toward the narrowing of the terminal aperture of the breach. All of these are of a very doubtful value, and will not be considered in this study. One of them, its object being the re-establishment of sphincteric action, and recently devised and recommended for another group of cases of incontinence, by Willems,[1] may be mentioned now. It consists in the implantation of the freed end of the rectum into a slit made by blunt separation of the fibres of an adjoining portion of the gluteus magnus muscle. The end of the gut is attached by suture to a corresponding aperture in the skin. This procedure was proposed as a complementary step of one of the modifications of Kraske's operation for excision of the rectum. It involves a great deal of dissection, a wide displacement of the gut to an inconvenient locality, and does not give much promise of success. As I have never had occasion to employ this procedure, I content myself by mentioning the idea.

As before stated, this last form of incontinence was justly considered to be incurable as far as full control of semiliquid fæces is concerned. There is good reason to say that now even these hopeless forms of the trouble have a fair chance of cure by a procedure that surgery owes to Gersuny. The procedure I refer to is torsion and implantation of the twisted end of the gut by suture. But we shall revert to this later on.

To complete the enumeration of conditions in which incontinence is observed, though the sphincter is still present but disabled, we have to mention various forms of ulcerative and stricturing proctitis, in the course of which parts of the sphincter are either destroyed by ulceration, or lose their active contractility by permeation with inflammatory deposit, and conversion of this into a dense, unyielding cicatricial mass. These are the cases in which stricture and incontinence may be simultaneously present. I have observed a number of instances of this state of affairs, and may be permitted to give an illustration. A young married woman, who had been cut for abscess of the Bartholinian gland accompanying a suspicious vaginal catarrh, returned to me after an absence of over two years with ulcerative and stricturing proctitis. Periods of most obstinate constipation, and just as obstinate diarrhœa alternated, and the woman presented a very marked state of febrile emaciation. The anus was the seat of a dense, massive stricture, extending an inch above the outer skin, through which an elastic urethral bougie of twenty-four French gauge could barely be passed. The sigmoid flexure and descending colon were perceptibly thickened, very painful to touch, and a mixture of pus, fæces, blood, and ropy mucus was continually oozing out of the small anal aperture. The stricture being divided by the knife, a wide area of ulcerated mucous membrane, occupying the rectal pouch, was exposed.

The ulceration extended a good deal beyond the visible portions of the gut, and this was ascertained by touch. Enormous quantities of slate-colored, putty-like, fecal matter were evacuated after this, and the stricture and ulcerations were subjected to a methodical treatment by dilatation, and by the application of various measures directed toward the maintenance of cleanliness in the rectal pouch. The fever diminished, but did not entirely subside, and the older ulcerations, situated near the anus, slowly healed one after the other. The patient would not hear of a colotomy, and finally withdrew disheartened from further treatment. It seemed to me then, that by means of colotomy the ulcerative process might have been brought to a standstill. After this the diseased part of the rectum might have been excised, and the colotomy wound closed. To-day torsion of the rectal stump would offer a very fair chance of the restoration of rectal continence.

[1] Centralblatt für Chirurgie, 1893.

These are, then, the various forms of rectal incontinence caused by disability of the sphincter.

Let us now consider those cases of incontinence which depend upon the absence of the sphincter muscle.

They are naturally divided into two groups. First come the cases of congenital defect of the sphincter, frequently observed as a complication of the various forms of imperforate anus and of atresia of the rectum. A large proportion of infants born with imperforate anus present other grave defects and instances of arrest of development, chiefly of the uropoetic system, which compromise their viability and lead to their speedy death. Those that survive proctoplasty, or proctotomy, and are provided with a sphincter, are fortunate and are few. Those that survive without a sphincter, will suffer from rectal incontinence.

Before proceeding further I have to state that R. Gersuny, of Vienna, in Austria, described, in No. 25 of the *Centralblatt für Chirurgie* of the year 1889, a novel and very ingenious process for the cure of vesical incontinence in women, which had yielded to him a brilliant success in one case. This process consisted in dissecting out of the entire female urethra, its torsion, that is, rotation around its own axis, and fixation of the twisted cylinder to the outer skin by suture. By establishing an elastic resistance, which could be overcome only by considerable intravesical and abdominal pressure, perfect continence was gained.

In July, 1893, F. F——, a boy, seven years of age, was admitted to the German Hospital with prolapse of the rectum and incontinence of fæces, due to congenital defect of the sphincter. He was born with an imperforate anus, for which proctoplasty had been performed shortly after his birth. There was present a prolapse of a cylinder of mucous membrane of about five inches in length, and on account of the continual oozing of fæces the child was excessively uncleanly. Remembering Gersuny's publication of 1889, I determined to try the identical method on the rectum. Accordingly, on August 12, 1893, the boy being anæsthetized, about two and a half inches of the lowermost portion of the rectum, including all of its coats, were freely dissected out. Then the free margins of the gut were secured at the four quadrants of its circumference by four artery clamps, and then twisted in an arc of three hundred and sixty degrees. I feared that this torsion would lead to an interference with the circulation of the gut, but the intestine did not change color and its circulation remained unimpaired, whereupon it was stitched to the outer skin by a dozen silk sutures. It was exceedingly interesting to observe, on introducing the index-finger into the anus, how great the resistance was that was offered. Though the wound did not heal entirely by primary union, the functional result was excellent, and both prolapse and incontinence were cured. I may add that the dissection was moderately bloody and not at all difficult. The patient was discharged on September 2, 1893.

Later on, in November, I had another opportunity to perform this operation, and while demonstrating the result to Dr. Lange, he informed me that someone had anticipated me in doing this same operation. Upon search, I found this verified by an article of Gersuny himself in No. 26 of the *Centralblatt für Chirurgie* of 1893, where he published the result of two successful cases of his own.

Let us now return to the consideration of the last group of cases of incontinence due to the absence of the sphincter. This most numerous group is made up of those instances in which the sphincter is extirpated by the surgeon in removing neoplasms of the rectum. Here torsion and fixation of the twisted stump will be an easy addition to the act of extirpation, or can be done later on with little risk, during or after the healing of the external wound. The amount of torsion required will be readily estimated by the resistance felt to the introduction of the index-finger. The smooth cylinder of the rectal channel will thus be converted into a rather close spiral twist, the

conditions being parallel to those of a smooth bore gun-barrel on one hand and of a rifle on the other. In leaving the twisted rectum the fæces will have to overcome the elastic resistance of normal living tissues, and must traverse the spiral course of a rifle projectile.

The second case operated on by myself and mentioned before was that of Mrs. Sarah G——, aged forty-one, who on February 21, 1893, underwent the operation of excision of the rectum for cancer at Mt. Sinai Hospital. Four and a half inches of gut, together with the sphincter, were removed after excision of the coccyx, and the stump was attached close to the sacrum. She made a good recovery. In November she presented herself again, complaining of incontinence due both to the absence of the sphincter and to a diarrhœal tendency. I found the anal aperture representing a flaring and wide funnel of mucous membrane, this excessive flaring being apparently caused by cicatricial retraction, its antero-posterior diameter being two and three-quarter inches, its lateral diameter two inches.

The advice to submit to Gersuny's operation was accepted, and accordingly this step was taken on November 28, 1893, at Mount Sinai Hospital. Dissection, the path of which lay mostly through cicatricial tissue, was remarkably unbloody. The peritoneum being incised, its free margin was stitched with catgut to the anterior aspect of the gut about three inches above the intestinal margin. After this the freed gut was twisted around its own axis in an arc of nearly three hundred and sixty degrees, and then attached to the margins of the external wound by a number of silk sutures. The wound healed in about three weeks. The patient's intestine is very sensitive to irritation, and in consequence of the absorption of mercury from the sublimate lotion used for irrigation during the operative work, a smart mercurial enteritis set in, which was overcome by the exhibition of opiates. There was considerable diarrhœa present, during which, however, the patient never failed to control her bowels. In presenting this patient to you I beg to direct your attention to the small amount of anal mucous membrane exposed; to the starlike concentric arrangement of the anal folds, very much resembling the aspect of a normal anus; and finally, to the close apposition of these folds to each other. On introducing the index-finger about two inches, especially if this be done immediately following defecation, a resisting ring of elastic tissue is encountered simulating a sphincter. This resistant ring of tissue is apparently corresponding to the place where the fixed portion of the gut ends and joins the twisted part.

There the effect of torsion must be most pronounced. Gersuny also mentions this peculiarity in his two cases. *A priori*, it may be assumed on general physiological principles that a new resistance having been created, a compensating hypertrophy of the muscular elements of the lower portion of the rectum down to the twisted part would result after a while. Whether this hypertrophy would embrace the twisted part of the rectum also, increasing its resistance and improving its function, or not, would be very interesting to decide by observation.

In conclusion, it may be added that torsion might be applicable to any portion of the large intestine, provided that the gut be first cut across completely, and is freed of its mesenteric attachment to a moderate extent. The distal segment can be either closed and dropped into the abdominal cavity, or can be attached to the margin of the external wound in the usual manner.

The great value of this simple and ingenious addition to the technique of intestinal surgery will be at once apparent to the practitioner, and its application in suitable cases can be warmly recommended.

OPENING THE CRANIAL CAVITY WITH A NEW SET OF INSTRUMENTS.

The Operation Illustrated from an Interesting Case, with a Report.

By J. S. PYLE, M.D.,

CANTON, O.

Surgeons find it very often necessary in brain surgery to secure an ample field for operation. To do this, in my opinion, there is no method that equals that performed with the diamond drills illustrated in this paper. The idea is not original. Drs. Hartley and Parker, of New York, advanced the principles of the operation, but I do not know how extensively these gentlemen have applied it. It is for the purpose of familiarizing the general reader with the operation, and extending its application, that an exposition of it is undertaken here. The step is too important a one in advance to reserve for the specialist in brain surgery. Every person who is likely to be called to render surgical aid in emergency cases of injury to the head ought to be able to make the operation. As an exploratory measure, the specialist will find that it answers every requirement without in the least sacrificing the protective envelope—the cranium. This is a very important consideration, and will, no doubt, be appreciated by those who frequently have occasion to extend the field of examination, but live in fear of the results from the loss of so much protection to the cranial contents. The extent of the cranium that can be loosened up and restored to its proper office has not been determined, and there seems to be no reason to suppose that any limit will be established. The bone that is turned out is not detached from the periosteum and scalp, and its nutrition is thereby preserved, making repair certain. The illustrations used to make this method clear are reproductions of photographs taken from one of my cases during the operation; the instruments are of my own device and are the result of a study of this class of work. The operation, whether performed for the relief of depressed

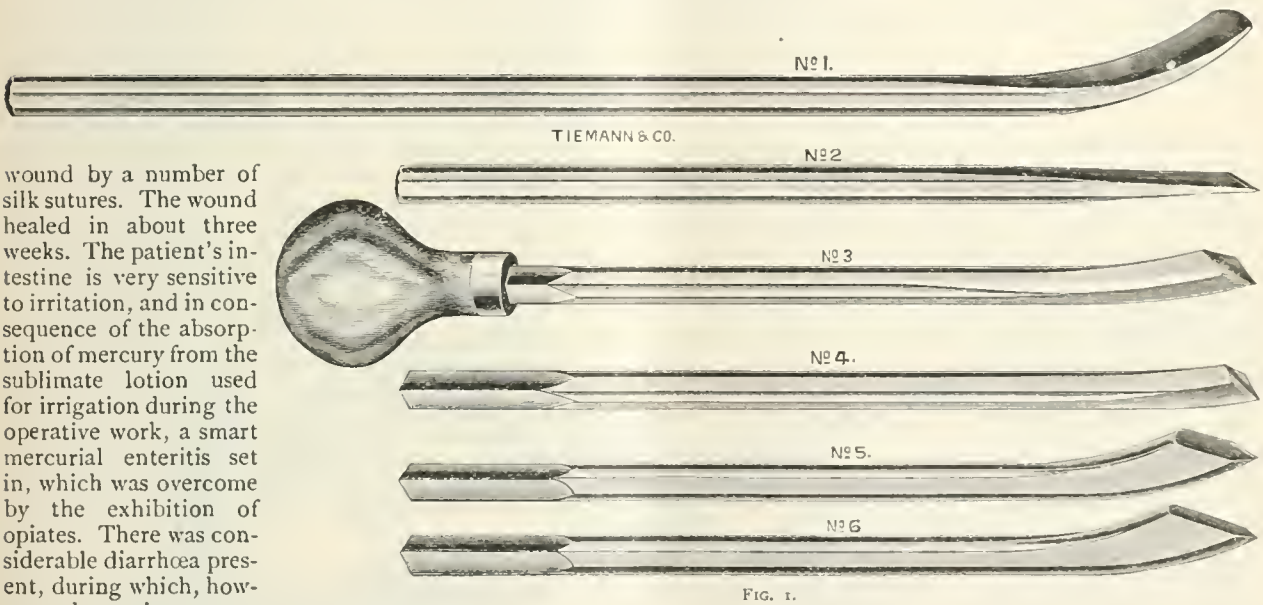

Fig. 1.

bone, or as an exploratory measure, is the same. The prerequisites are the necessary instruments, consisting of those shown in Fig. 1, a scalpel, hæmostatic forceps, needles, mallet, sponges, irrigator, etc., and antiseptics. There should be four assistants. The patient should have the entire head shaved and the scalp cleaned with a

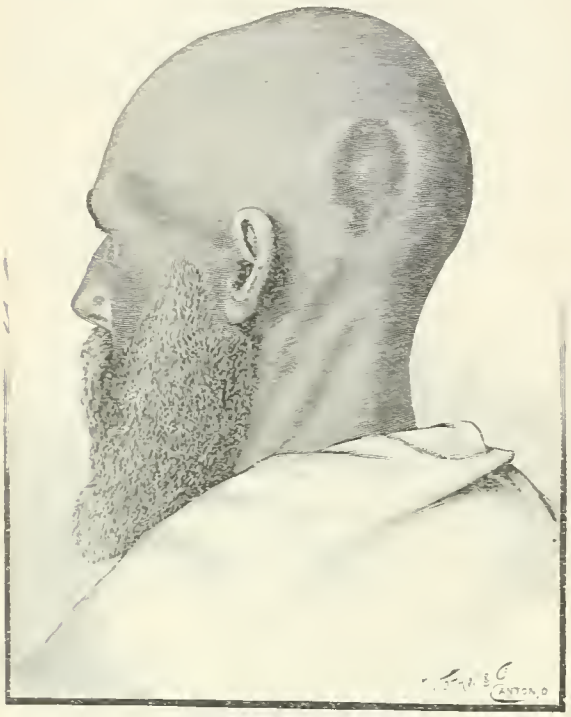

Fig. 2.

brush, soap, and water, and the head then treated with a five per cent. solution of carbolic acid. Our Fig. 2 shows a depression of the occipital bone, and the head after it has received the preliminary treatment. The site of the operation might with advantage be further protected by covering it with a napkin soaked in the antiseptic fluid until the instant of beginning the incision. In all cases the incision through the soft parts and bone should be square or U-shaped; one side of the square, or the base of the U-shaped piece of bone thus mapped out should not be divided in the incision, the bone being simply broken away in the manner shown in Fig. 4, forming a flap consisting of cranial wall, periosteum, and scalp. The incision in the case shown in the illustration is U-shaped, with the base directed downward and made to include the whole area of depression. A scalpel is used to divide the scalp and periosteum. The latter should be thoroughly severed so as to avoid any denudation of the flap of bone when the cranium is cut through. The diamond points shown at Nos. 3, 4, 5, and 6, in Fig. 1. are the instruments used to effect the separation of the bone. This step is illustrated in Fig. 3. The instruments are made of the very best steel, and in four graduated sizes, so that when commencing the operation with the largest, as the excavation proceeds and the furrow grows deeper a smaller size may be used, thereby reducing the cutting surface and facilitating the progress of the operation. Nos. 5 and 6 are specially made to work at the required depth and with the necessary precaution to the underlying membranes and brain substance. They are curved at the cutting end, which makes it possible to regulate the depth of the stroke to a nicety. This is of the greatest importance, as when the internal table is reached care must be exercised not to damage the underlying dura mater. Accidents to the dura mater, however, are not near so likely to happen in this operation as with the trephine or electric saw. Depressing the handle of the instrument raises the cutting point, and this may be so directed that the internal table may be cut through with rapidity without doing harm.

One ball shaped handle is provided for the entire set, and when used it is slipped on the instrument and held in the palm of the hand. The position of the right hand grasping the instrument, and that of the left steadying the head of the patient during the operation, is well shown in Fig. 3. The bone is divided by repeated strokes in the same manner that a wood-engraver cuts a deep furrow in a piece of wood. In beginning this part of the operation No. 1 is operated with the mallet. The handle is left off and the instrument is driven along the line mapped out, by gentle taps, until the furrow is of sufficient depth to retain the point of the instrument, when the hand may be used exclusively to propel it. From this on until the internal table is reached, the cutting may be done with the greatest rapidity. When the bone has been completely divided as far as intended, it will be next in order to turn out the section bounded by the furrow in the manner illustrated in Fig. 4. The instrument used is that shown at No. 1, in Fig. 1. There are three of this kind, one is placed in the middle of the piece of bone to be elevated, and the remaining two on each side at the point where the bone is to be broken through. An assistant is needed to manipulate the instrument occupying the middle and upper part of the piece to be raised, while the operator takes charge of the other two, and by simultaneously raising and lowering the handles of the three instruments, the bone is broken. This step should be done

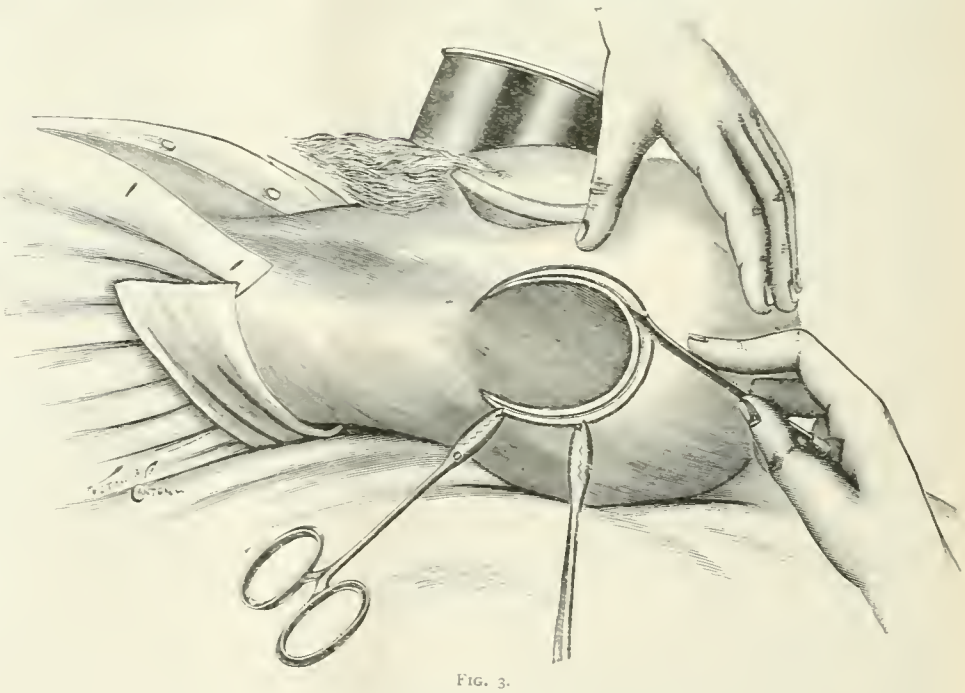

Fig. 3.

deliberately and gently, so as to allow the dura mater time to peel off without injury or causing undue hemorrhage. If this is followed the fracture will also take the direction required. The instruments are used as levers and are curved slightly at one end, which is somewhat flattened and edged so as to make them easy to introduce beneath the bone and between it and the dura. The cranium surrounding the piece to be elevated is used as a fulcrum.

The instrument shown at No. 2, in Fig. 1, is for the purpose of cutting away any spicula that might be left after the fracture. The use of the mallet is again required to accomplish this. During the whole operation the wound should be irrigated with a weak antiseptic fluid. A one per cent. carbolic solution is preferable. If the operation is to be continued upon the brain this may at this juncture be dispensed with and pure distilled water used.

Fig. 5, introduced to show the condition of the piece of depressed bone found in the case used to demonstrate the different stages of this operation, will also illustrate the step just before proceeding with a cerebral operation or concluding the one under consideration. If the depression is not great, all that is necessary to be done is to replace the piece turned out by stitching the fresh borders of the corresponding soft parts, the expansive force of the brain when the calvarium is detached is sufficient to produce enough outward displacement to prevent any return of the compression of the brain. On the other hand, if the bone is very much depressed the piece can be broken and returned in the same manner. To secure the proper convexity of the part thus operated upon, a silver pin may be thrust through the soft parts, between the scalp and the periosteum, from one side of the flap to the other, and extending far enough through on both sides to rest on the border of the solid cranial wall. By bending the silver pin, giving it the same convexity as the natural cranium, the normal condition may be restored. It may be necessary in extreme cases to use a number of these pins; as they do not irritate, no harm can come from this source. Two are usually sufficient, introduced at right angles to each other. The operation being completed as described, the next and the last thing to be done is to arrange the dressings, which are simple, but contain the strictest observation of antiseptic precautions. The wound is first bathed with a five per cent. solution of carbolic acid, then dusted with iodoform, the powder being rubbed along the approximated borders.

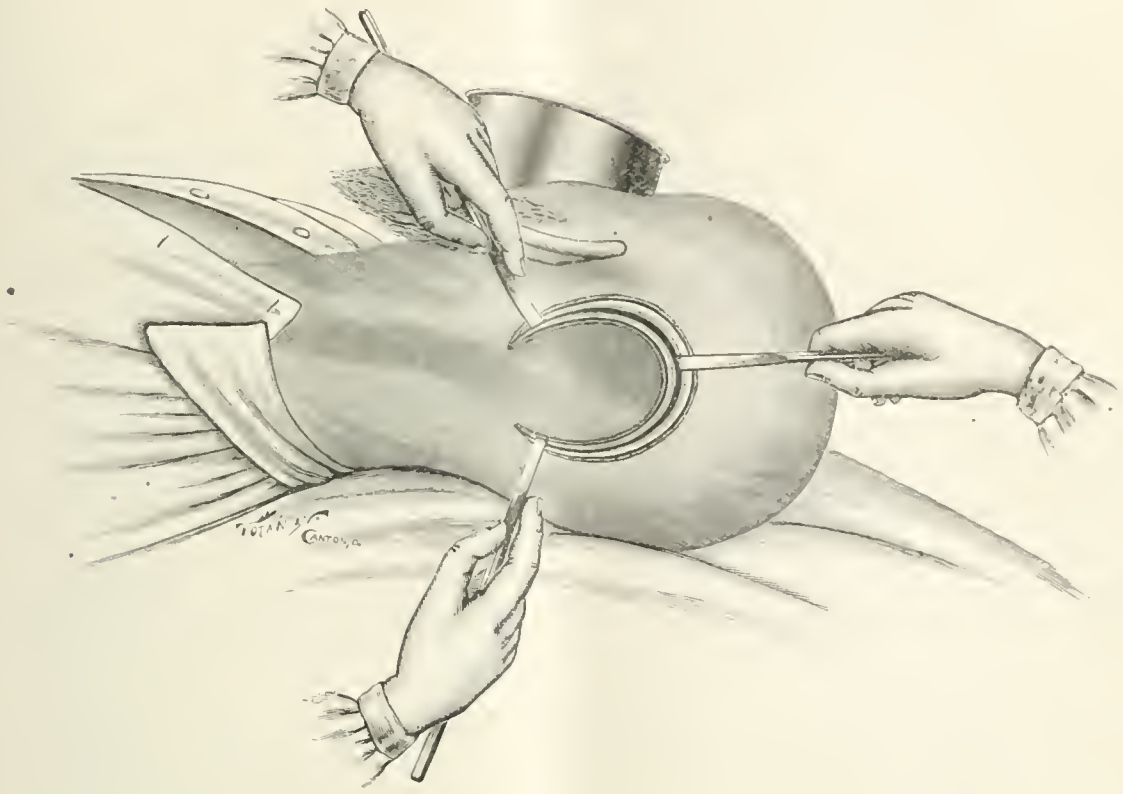

Fig. 4.

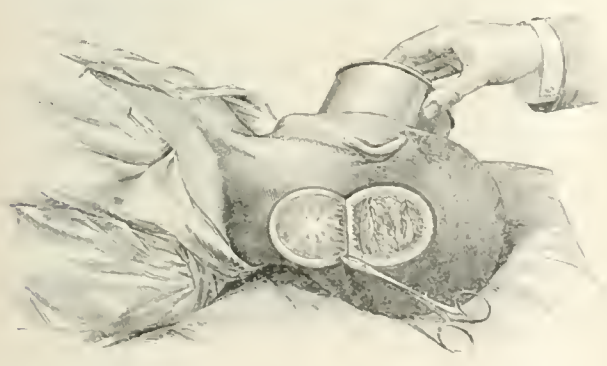

Fig. 5.

Gauze soaked in strong carbolic solution is next applied. Several layers cover the wound, extending for some distance around, so that when the dressings become saturated with blood and harden it produces an excellent splint, which affords ample protection to the underlying parts during convalescence. A layer of cotton further protects the wound, which is covered with oil-silk and the dressings made secure with rubber plaster. The stitches may be removed and the wound dressed at the end of the second week. The wound should not be opened before the expiration of this period unless occasion demands, and even at this time the dressings need not be removed unless the patient is really disturbed by them. The wound almost invariably heals very rapidly. The silver pins may be removed after the case has entirely recovered or bony union has taken place. Our case that illustrates this article was injured six years ago by a hard-rubber ball, driven by a base-ball bat, striking the head at the point of depression. Later, severe headaches with mental irritability were induced which continued to grow worse, until serious mental derangement was feared. The pain was referred to the point of depression, radiating from there to the eyeball on the same side. The operation as herein described entirely relieved the symptoms, and four months have passed without any return. The relief was immediate, and the patient expressed himself the next day as having never felt better since the accident had occurred.

Tuberculosis in Cattle.—The valuable blooded stock, numbering nearly a hundred head, belonging to the State Hospital for the Insane at Middletown, are affected with tuberculosis, and two-thirds have been condemned.

TREATMENT OF DEPRESSIONS IN THE SKULL OF THE NEW-BORN.[1]

By DAVID D. JENNINGS, M.D.,

NEW YORK.

ATTENDING SURGEON, BELLEVUE HOSPITAL, OUT-DOOR DEPARTMENT, ETC.

This subject has not had the consideration its importance deserves, for, while it is not a common injury it is liable to occur in the hands of any general practitioner, not only in forceps and breech cases, but also in unaided deliveries.[2] As the treatment of these cases is entirely overlooked in the text-books, I bring it to your attention with the hope that a satisfactory plan of treatment will be outlined, so that, in these days of advanced cerebral surgery more will be done than leaving them to nature, as is the treatment of to day.

By depression I refer especially to the indenting or bending in of the bone, with or without fracture, not the simple overlapping of a suture. It is most commonly found in the frontal and parietal bones, and less frequently in the temporal and occipital.

The books say that these depressions come right of themselves, due to the intra-cranial pressure and the resiliency of the bone, and give the remarkable case of Duges[3] as an example. He gives an instance of great depression in one of the parietal bones, not followed by any serious consequences. The child was delivered by the feet, through a pelvis of which the conjugate diameter was estimated at three and a quarter inches. Powerful traction upon the shoulders and upon the lower jaw was necessary to bring the head past the obstruction, and the parietal bone, which was in relation with the sacro-vertebral angle, presented a depression half an inch in depth and two inches in width. The infant was resuscitated with difficulty, then had convulsions, but in a few days was quite well, and in fifteen days the depression had entirely disappeared.

The fortunate outcome of this case would in these days be no excuse for allowing a child to lie in convulsions for days, when we have a means of prompt relief at our command. It is unreasonable to expect this favorable outcome in the majority of these cases, and, when we consider the serious consequences of these early convulsions, we are justified in removing the cause.

These cases do not always come right of themselves, and, from the cases that have come under my observation, I would say that frontal depressions rarely do. Cases of marked depression in each of the cranial bones are on record,[4] and serious consequences have followed.

Dr. Wharton Sinkler[5] says: "A few days ago I saw a child with right hemiplegia, and the mother stated that the child had been delivered by forceps, and that, immediately after birth, there was a deep depression behind the left ear. I found upon examination of the child, who was now sixteen months old, that the depression still existed in the left mastoid process. There was right hemiplegia present. The right leg was spastic, and the movements of the arm limited and inco ordinate."

Mr. Charles Mercier[6] reports a case of hemiplegia, from injury to the cranium by forceps during delivery: "Mary Ann B——, aged thirty-seven, has right hemiplegia. The arm is quite incapable of voluntary movement, is smaller in all its dimensions than the opposite limb, and is severely contracted, so much so that the palm and palmar surfaces of the extended fingers lie in contact with the front of the forearm. The right leg is paralyzed and contracted, but to a less degree than the arm; the right foot is smaller than the left, and owing to the contractions of the calf-muscles, she is unable to put her heel to the ground.

"On the left side of her head is a deep curved groove, beginning vertically over, and one inch above, the ear, and running forward for about an inch. It then curves upward with a bold sweep, and, becoming shallower, finally runs backward and is lost between the vertex and the parietal eminence. The groove is about half an inch wide, the concave edge steep, the convex edge bevelled. Over the anterior inferior angle of the parietal bone, where the groove is most marked, it is about an eighth of an inch deep; but the tension of the skin serves partially to obliterate the depth, which is found by the touch to be greater than appears. Over this portion of the groove is a considerable cicatrix. The patient has been hemiplegic from birth, and has had the groove on her head also all her life. The mother had often told her that 'instruments' were used at her birth."

After giving this history he makes the following remarks: "There can be no doubt about the obstetric origin of this deformity and paralysis; and, having regard to the high elasticity of the new born skull, and the deep indentations often visible on the heads of children delivered by the forceps, indentations not only in the caput succedaneum, but actually involving the bones, it is questionable how far this extreme case is a representative of others in which, the violence being less excessive, the external traces do not persist, but the damage to the brain remains irretrievable. Cases of congenital hemiplegia are common, and in two cases I have been able to prove that the arteries supplying the atrophied convolutions were pervious."

Lusk,[1] when called upon to settle a dispute which had arisen between two practitioners as to the advisability of trephining the frontal bone for a depression, says: "I am not sure that this might not be good practice in some instances, but so far we have had no experience as regards results."

I have the pleasure of reporting a successful trephining for this condition, which I did, at the urgent solicitation of the father, on an infant forty hours old. On February 26, 1893, I was called to see an infant who had just been delivered by the forceps. The left frontal bone was deeply depressed, presenting a concave instead of the usual convex surface. The depression, smooth and cup-shaped, was more than half an inch below the surface, and was so disfiguring that the father wished something to be done at once for its relief. In the absence of symptoms I advised delay to give nature a chance.

Forty hours after birth, the head having assumed its normal outline, with no improvement in the depression, I operated, with the aid of Dr. Philip Scheu, after suction with a cupping-glass, as recommended by Paré and Hildanus in fractures in young children, and practised successfully by Larkin[2] in a similar depression, had failed.

The scalp having been thoroughly cleansed, a Y-shaped incision was made over the centre of the depression, the periosteum incised and stripped back sufficiently to apply a small trephine (half an inch in diameter). A button of bone of considerable thickness was removed, and the surrounding bone lifted into position with an elevator. After cleansing the wound with a weak carbolic solution the button was replaced, and the wound closed with catgut sutures, using a few strands of catgut for drainage. Antiseptic dressings were applied, and the infant was soon quietly nursing at its mother's side.

The operation was simple, and apparently without shock. No anæsthetic was employed, and it was not necessary to tie a vessel. The catgut drainage was removed on the following day. The wound healed by primary union. The child slept and nursed well, and made an uneventful recovery.

Gross,[3] in speaking of the operation of trephining in early childhood says: "The utmost caution is required,

otherwise, as the skull is very thin and destitute of diploë, there will be great danger of injuring the membranes of the brain, the more especially as the dura mater adheres with extraordinary firmness to the inner surface of the cranium."

In my case I did not experience any difficulty in removing the button after it was separated, and, in the cases I am about to refer to, the dura mater must have been separated from the bone for as much as an inch without any injurious result. While this is the first trephining, it is not the first operation performed for this condition.

Dr. Tracy [1] raised a depression in the frontal bone by making an incision just forward of the fontanel, and passing in a small pair of curved scissors (which he used as an elevator) between the bone and the dura to the centre of the depression. After two or three unsuccessful attempts, he succeeded in snapping the bone into place. The child was well years afterward.

Dr. Sinclair [2] reported a deeply indented frontal bone occurring in a forceps delivery, but not due to the instruments, as the forceps' marks were on other parts of the head, and says: "The disfigurement was so marked that the child's father declared he would rather it should die than grow up with such a mark." "As no external pressure produced any effect an incision was made near the anterior fontanel, into which an elevator was introduced and passed through the frontal suture, between the dura mater and frontal bone, to the point of depression. After three ineffectual attempts the depressed bone was raised to its normal position. Water-dressings were applied, and the child recovered perfectly."

Dr. Irving W. Smith [3] reported last year two cases of depression due to instruments. The first infant had a fronto-parietal depression, and developed obscure symptoms from which it died after about twelve days. In the second case the depression occupied the right frontal bone, and was three inches long, two wide, and half an inch deep. The child was constantly crying, and nursing and sleeping little. Profiting by his experience in the former case, he operated on the fourth day, raising the depression, after dividing the bone with a Hey's saw transversely to the axis of the depression, with an elevator applied successively on either side of the saw-track. A slender, long spicule was removed. The operation under anæsthesia was without shock, and the child slept and nursed normally from the hour of the operation.

These four cases are all I have been able to find where an operation has been performed. They were successful, and, if serious consequences do follow as a result of these depressions, these infants have escaped.

I believe you will all agree with me that, if symptoms accompany the depression, it is our duty to operate at once; but how shall we treat that equally large class of cases where there are no immediate symptoms? Here there are two indications: 1. To prevent subsequent brain trouble. 2. To relieve the deformity.

The first indication is the only one to be seriously considered, as the growth of hair would hide the disfigurement in any region but the frontal.

Fritsch regards these cases as generally fatal, for, even if the child cries lustily after birth, in a few hours it becomes drowsy, and dies from stupor.

Schroeder [4] collected 65 cases of spoon-shaped depression. Of these 32 were fatal and 33 survived. Of the fatal, 22 were born dead, and 10 died shortly after birth.

As we have no collected testimony as to the results of these depressions in infants, we are compelled to make a comparison with the same class of cases in older children and adults. This will not be entirely satisfactory, as in infants we have the presence of fontanels and sutures to allow of some compensation. We have, however, the cases of Sinkler and Mercier, previously quoted, to show that permanent injury does sometimes follow these depressions, and it is a question how many cases of hemiplegia are due to the results of these injuries after the depression itself has disappeared.

It has been, and still is, a disputed point as to whether a simple depression in the adult head does cause symptoms, and also whether an operation for its relief is justifiable. The latest text-books advise us, and it is the practice in our large hospitals, to operate for the relief of simple depression, and so avoid the subsequent dangers, *i.e.*, insanity, epilepsy, persistent headache, etc.

Dr. Agnew [1] recently writes: "The doctrine that depressed fractures of the skull without symptoms required no operative interference, a doctrine, which in the past has been so deeply rooted in the professional mind, I hold to be responsible for many, very many, of the unfortunate sequels of head injuries. However small may be the depression which follows a fracture of the cranium, save in one or two localities, it will encroach enough upon the dural nerves to cause more or less irritation, which, though insignificant at first, and not at all recognizable to the consciousness of the patient, yet eventually that irritation will be propagated to the meninges, and later on to the cortex and brain ganglia, until finally the paroxysmal explosion occurs, and then, even when the initial lesion is removed, the slowly established habit, created by years of excitation, will remain as an ineradicable legacy. No amount of foresight can determine what happens to the inside of the skull, after the reception of an injury, by the inspection of its external surface, the physical properties of the two being so very unlike. Whenever, therefore, in my judgment, the profession can accept the doctrine that all depressed fractures of the cranium, however slight may be the depression, and entirely irrespective of pressure symptoms, are proper subjects for trephining, then will traumatic epilepsy largely disappear from the list of surgical diseases."

Some claim that you must have a spicule of bone irritating the brain; a laceration of, or hemorrhage, causing pressure on the brain to produce symptoms; but a case that came under my observation while interne at Bellevue Hospital inclines me to side with those who believe that depressed bone alone will cause irritation. A child, three years of age, was carried into the hospital in his mother's arms to have a scalp wound dressed. While waiting his turn the boy had convulsive twitchings of eyelid and upper and lower extremities of the left side. Right side motionless. He had fallen from a truck upon the top of his head, and received a compound depressed fracture of the right parietal eminence. After the cup-shaped depression was raised by trephining just outside of fracture, the symptoms of compression were immediately relieved, and the boy felt so well on the following day that we kept him in bed with difficulty. There was no evidence of injury to the brain or membranes, and the symptoms appeared to be due entirely to the depression.

It is also a fact that the simple removal of depressed bone has cured cases of epilepsy,[2] paralysis,[3] and headache that have lasted for years.

If, then, in the adult, where the cortex is alive to the least irritation, it is unwise to allow a depression without symptoms to remain untreated, is it not also unwise to wait for symptoms in infantile depressions, when it is a fact that very great damage may be done to an infant's brain, because the cortex is undeveloped, without producing a cerebral symptom? In Dr. West's [4] case, the child did not present a symptom of injury to the head, with the exception of a hæmatoma of the scalp, until the twenty-third day after birth, when it became drowsy and had convulsive twitchings of the face. On the twenty-sixth day it developed general convulsions and died.

[4] Transactions of London Medico-Chirurgical Society, 1845, p. 397.

At the autopsy a fissured fracture of the parietal bone was found, with an effusion of blood more than half an inch in thickness, occupying the entire fossa of the parietal bone, all firmly coagulated and not of recent date. The right hemisphere was pale, bloodless, and very soft. There was no fluid in the ventricles, and but little blood in the sinuses. In this case "no symptom of affection of the brain appeared till the twenty-third day, and death took place on the twenty-sixth."

E. Barrie[1] reports the case of an infant, one month old, who at birth presented a deep lozenge-shaped depression occupying the space between the anterior fontanel and the bos frontis, who died suddenly, the only sign of sickness being a convulsion ten days previous, after which the infant was as well as ever. At the autopsy the organs were found normal, and there was no alteration in the brain with the exception of an excavation to allow the depressed bone to rest in.

When shall we operate?

Immediately, if there are symptoms.

If there are no symptoms we may wait a few weeks to give nature a chance. If she is to succeed she will do most of her work in the first few days. Whatever improvement takes place after that time is more apparent than real, as it is very probable that the concavity is partially filled with new tissue. I say this because at some of the autopsies the bone was unnaturally red, and the periosteum very much thickened. As some French writer puts it, the periosteum was "recovered."

How shall we operate?

By trephining, as it is applicable in all situations; is safer than using the Hey's saw, and besides giving a better opportunity to work, it allows of the inspection of the underlying parts.

Conclusions.—1. Use pneumatic traction. If this fails, trephining is the best operative procedure.

2. Trephining, *per se*, is not a dangerous operation.

3. The removed button of bone can be replaced with good prospect of its union, on account of the vascularity of the bones at this age.

4. Frontal depressions rarely right themselves.

5. Operate at once if there are symptoms.

6. If the depression is still exaggerated at the end of two weeks, operate to prevent subsequent brain trouble, and relieve the deformity.

333 East Twentieth Street.

Clinical Records.—A writer in a journal narrates the following experience: "I was called out one morning at three to see a lady who was 'very ill.' Upon arriving at the house I was shown into a room where a lady was sitting in a composed attitude. I at once asked her where I was to find my patient. She replied with calm deliberation, 'I am your patient.' 'Indeed. What is the matter?' 'If you will take a chair,' said the lady, 'I will tell you. The fact is that I fear I have taken to drinking.' 'I am very sorry to hear it. When did you make the mistake?' 'I am not quite confident as to dates, but as well as I can remember it was in the year 1866—early in 1866.' 'But do you consider it was necessary to knock me up at 3 A.M., in 1893, to see you because you took to bad habits in 1866?' I thought that was the wisest course to pursue."

Continental Vivisectors.—A memorial has been presented to the British Home Secretary by the Victoria Street Anti-vivisection Society, signed by 15,727 persons, requesting the Home Secretary to withhold licenses for vivisection from applicants of foreign birth or extraction. The memorialists state that it is the prevailing opinion that foreign vivisectors are less humane than Englishmen, and that being so they note with alarm that in the inspector's annual reports a considerable number of names of licensees obviously not English. The Home Secretary is scarcely likely to accede to such an application.

PANCREATIC CYST—URETERO-VAGINAL FISTULA, THE RESULT OF VAGINAL HYSTERECTOMY—SUCCESSFUL REIMPLANTATION OF URETER INTO THE BLADDER.

By W. J. MAYO, M.D.,

ROCHESTER, MINN.

SURGEON TO ST. MARY'S HOSPITAL; PRESIDENT OF MINNESOTA STATE MEDICAL SOCIETY; MEMBER OF STATE BOARD OF HEALTH.

1. Pancreatic Cyst.—The pathology of this rare affection has advanced but little since Dr. Senn wrote his classical paper upon the "Surgery of the Pancreas," in 1885; but workers in many fields are reporting cases and making comments upon the prominent features which characterize the disease; and out of the growing material at our disposal more exact pancreatic surgery will evolve. For the purpose of adding to the literature of the subject, I report the following typical case:

Mrs. J. S——, Minneota, Minn., Icelander, aged twenty-eight; married; mother of one child aged eighteen months. Admitted to St. Mary's Hospital September 30, 1893, with the following history:

One month after the birth of her child she first noticed a tumor just to the left of the middle line between the umbilicus and the margin of the left costal cartilage. The enlargement gradually increased in size, giving rise to a feeling of pressure and weight; during the past four months it has grown rapidly, is more painful, and colics or cœliac neuralgias are of frequent occurrence.

There is marked digestive disturbance, partly due no doubt to the fact that she is two and one half months pregnant at the present time. Her general health is failing, and she has lost fifteen pounds in weight. Physical examination reveals a smooth, rounded, and somewhat elastic tumor in the left hypochondriac region, the size of a child's head, slightly movable in a direction toward the umbilicus. Tumor of the spleen was easily excluded, as there was intestinal percussion-note to be obtained anterior and external to the enlargement, showing it to be retro-peritoneal in origin. Renal cyst from the upper part of left kidney was ruled out with more difficulty. The urine was normal and there was no indication of urinary disturbance whatever. Insufflation of the colon with air by the rectum showed that the descending colon passed external to the tumor, between it and the loin, and that the transverse colon lay just below it, while the stomach percussion-note was immediately above. A diagnosis of pancreatic cyst was made by exclusion, admitting, however, of a possibility of cyst of the upper part of the mesentery or hydatid. On October 3, 1893, with the assistance of Dr. C. H. Mayo, and in the presence of Drs. Stinchfield, Witherstine, and Dugan, an incision was made in the median line above the umbilicus. The tumor was found to lay between the stomach and the colon, under the omentum, but too far to the left to be fixed in the opening; a second incision was made in the left semilunar line from the ninth costal cartilage downward, the gastro-colic omentum under which the tumor presented was stitched to the parietal peritoneum and to the tumor wall, and the cyst opened and drained of about one quart of straw-colored pancreatic fluid of the consistency of sirup. Tubular drainage was established, with definite healing in five weeks. The course of the pregnancy was uninterrupted.

2. Uretero-vaginal Fistula, the Result of Vaginal Hysterectomy—Successful Reimplantation of Ureter into the Bladder.—Certain post-operative conditions occur with sufficient frequency to deserve special consideration, as in ventral hernia. In the newer fields of surgery untoward results, necessitated by pathological conditions of like unpleasant character, occur, and among these none are more distressing than urethral fistula. Surgery of the ureter in the upper part of its course has been most ably worked out by Christian Fenger, Weller van Hook, Howard A. Kelly, and others, and the possibility of its complete obliteration with atrophy of the corresponding kidney proved by the experimental work of F. B. Robin-

son. Uretero-vaginal fistula will occasionally occur as a result of vaginal hysterectomy, and more than forty cases have been reported; half of these were, however, due to parturient injuries. The literature of this particular form of accident is very scanty, and those interested in the subject will find a review of a case reported by L. Picqua, and of a paper by M. Bazy, both of Paris, in the *Annals of Surgery* for November, 1893; also a review of a paper by L. H. Dunning. This latter excellent paper can be found in full in the *Annals of Gynecology* for August, 1893. The following case is reported:

Mrs. A. B——, American, aged thirty-six, Winona, Minn. On July 6, 1893, at St. John's Hospital, Winona, Minn., with the assistance of Drs. J. B. McGaughey, C. H. Mayo, and D. Pritchard, I removed by vaginal hysterectomy a large carcinomatous uterus. The operation was rendered very difficult by reason of old inflammatory adhesions to the right and posterior as high as the fundus of the uterus, Douglas's pouch being obliterated. The operation was done by ligatures excepting the upper part of the right broad ligament, when the nature of the tissues rendered clamps necessary. In three weeks she was able to be around, but recovery was retarded by a constant flow of urine from the vagina. By injecting the bladder this viscus was found competent, and by collecting the amount of urine flowing from the vagina, it was found to be equal in amount to that expelled from the bladder, and normal in other respects. A probe introduced into the fistula at the apex of the vagina passed to the right, making it evident that the right ureter was severed in the infiltrated tissues at a point about one inch from its cystic termination. On September 10, 1893, she came to St. Mary's Hospital, Rochester, Minn., and by means of a plastic operation on September 12th, the end of the ureter was freed; a short channel lined with mucous membrane of the vagina was formed, connecting the ureter end with the bladder. Union was perfect so far as the channel was concerned, but failed at the bladder end, and the opening into the bladder promptly healed, leaving the fistula at a new point against its posterior wall. Three weeks later, October 3d, she was again etherized, a flap of vaginal mucous membrane was raised just below and behind the fistula, forming a collar to its lower lip. A curved incision was now made into the bladder, just above and in front of the fistula. A long piece of one-eighth inch rubber tube was carried through the urethra, bladder, and out the cystotomy opening; its upper end was cut obliquely and several lateral openings were made along the upper three inches; this end of the tube was now passed up into the channel previously formed about one inch, and against the ureter end, and secured in this position by a catgut suture. The collar of mucous membrane behind and below the fistula was now turned forward and sutured by buried catgut to the mucous membrane of the bladder, and the posterior lower edge of the cut bladder wall firmly secured to the denuded surface below and behind the fistula by silkworm sutures. The rubber tube carried the urine from the end of the ureter through the bladder, and by its openings in the bladder drained that viscus and prevented tension, its external end passing through the urethra and into a bottle. The bladder was washed with boracic acid solution through the tube daily, and boracic acid given internally to keep the urine acid. By softening of the catgut sutures which held its upper end in position the tube was easily removed on the eighth day, and was not incrusted. No leakage by the vagina took place at any time, and the silkworm sutures were removed in sixteen days. There was but little vesical irritability after the first two weeks and the patient was discharged in three weeks, with a vagina but little shortened from its normal length.

Rheumatism in Past Ages. — Some very ancient Egyptian mummies have recently been unearthed, the bones of which present evidences of chronic rheumatism.

ON THE TREATMENT OF COMPOUND FRACTURES.[1]

By GEORGE W. CRILE, A.M., M.D.,

CLEVELAND, O.

PROFESSOR OF PHYSIOLOGY, AND LECTURER ON MINOR SURGERY, MEDICAL DEPARTMENT UNIVERSITY OF WOOSTER, CLEVELAND, O

Indications for Amputation.—If the blood vessels be injured to such an extent that a sufficient nutrition, direct or collateral, is impossible, amputation is clearly indicated. In any case, *if in doubt, wait.*

Injury to the Nerves.—Laceration of great nerve-trunks takes the *rôle* of a serious complication, but in itself is not a sufficient indication for amputation. The injury to the bone is practically never a sufficient indication in itself for amputation; although the bone may be comminuted, the fragments displaced, even detached, repair will, by appropriate treatment, usually follow.

Indications for amputation in cases of compound fractures are based upon complications, the loss of blood-supply, and the destruction of the nerve-trunks; if in doubt, revise the wound by cutting off the shreds of tissue that will probably suffer molecular death, cleanse the parts, provide free drainage, and place the limb in a moist, warm antiseptic dressing, keep at the temperature of the body, the part somewhat elevated, and you can safely wait the clearing up of indications. In these cases in which the limb is placed on probation the treatment should be the same as if there was no doubt that the limb could be saved. In this manner I have kept for a week a limb that had suffered molecular death in a compound dislocation without a rise in temperature, without pain; and when the time came for an amputation the field of operation was aseptic, and recovery was rapid. If the wound be kept aseptic, the risk to life in waiting is not great. When amputation is not indicated each case must be a law unto itself, and yet there are certain principles which underlie all compound fractures.

Treatment of the Bone.—Cases in which the fragments can be reduced and held in apposition by the ordinary resources—position, splinting, and extension—present no greater difficulty in treatment, if the wound be aseptic, than simple fractures.

If reduction cannot be perfectly made, enlarge the opening in the soft parts, and place the fragments in their proper position. In any case, if necessary, administer an anæsthetic. Reduction of fragments must be made as perfectly as possible. If there is marked over-riding of the fragments, and it is apparent that retention in apposition cannot be maintained by the ordinary methods, then the surgeon should resort to some method of direct fixation to accomplish this end. I have found ligatures of silk very satisfactory. If aseptic, they may be cut off closely and buried in the wound, and not removed.

In order to insure against the slipping of the ligature I have resorted to making a small groove with a saw in each fragment. The ligature placed in this groove cannot slip. As an illustration the following case is given:

A boy, twelve years of age, sustained a multiple fracture of the humerus. The bone was fractured at three places; the middle segment, about two inches long, was also split longitudinally. One of these fragments projected through the wound. The lower fragment was also split longitudinally into the elbow-joint. The upper fragment was comminuted at its junction with the middle fracture, some parts of which were completely detached. The opening in the soft part was enlarged, the bone exposed, and the fragments adjusted, grooves sawed in the ends at the point of application of the ligature, the fragments were closely tied together in four places with strong silk. The wound was partially closed, free drainage provided, and lateral splints applied. After these fragments had been tied together like a bundle of sticks the bone would easily support itself, and when the arm was lifted

[1] Read before the Northwestern District Medical Society, December 7, 1893.

by the elbow the contour was not altered. Splints seemed superfluous, as the bones united, leaving the humerus inappreciably shortened. If this case had been treated by means of a bone ferule, owing to the peculiarity and number of the fractures, the application would have necessitated almost complete detachment of the bones from the soft part; not only this, but it would have been necessary to have applied three or four ferules, which I am sure would have very much reduced, by reason of the destruction of the soft parts and the presence of so much foreign matter in the tissue, the chances for a good result. The advantage I have found in using silk ligatures is that their application is simple with a blunt needle or pedicle needle, and if these are not at hand a curved needle with its point directed close to the periosteum of the bone may be used. There is a minimum mechanical interference. It is unnecessary, then, to turn the bones out from the soft parts, and a further destruction of the blood supply is avoided. In a number of cases in which I have used it, it has always proved a sufficient means of fixation.

In simple oblique fractures with great displacement the ligatures, I believe, might be applied with great advantage. The bone lesion in compound fractures is treated on the same principle as that of simple fractures, lateral displacement and rotation being prevented by suitable splinting.

Treatment of the Soft Parts.—The tissues should be carefully revised by snipping off shreds and particles whose vitality has been destroyed. Muscles may be trimmed off and brought together, tendons sutured, and care should be taken to place the tissues in their normal relation. Above all, as long as there exists a doubt as to the infection of the wound, provide free drainage, and if the natural opening does not present dependent drainage, the establishment of a counter opening should be considered. After forty-eight hours, if the wound proves to be aseptic, drainage may be removed, and the wound closed; if not, the wound and soft part should be treated in exactly the same manner as if no fracture existed. The skin at the opening of the wound, unless perfectly clean, should have the margin continuously removed. Nerve-trunks, if severed, should be immediately sutured by the direct method, end to end, or indirectly, by fixing each end of the nerve-trunk in hollow, perforated, decalcified bone. Ordinarily I prefer to make for each fracture a splint from bass-wood. With cotton, adhesive plaster, bass-wood, and a sharp knife, a splint may be made for almost any possible fracture. There are splints of excellent devices on the market, but the objection to their indiscriminate use is that very few of the models will fit the limb under consideration, and the contour of the limb will adjust itself to the idea of the manufacturer, instead of the idea of the manufacturer the contour of the limb. In using a plain piece of bass-wood the contour of the limb may be duplicated by padding of the splint, thus applying a greater pressure here and a lesser pressure there. Selective padding, judiciously made, will safely accomplish these ends. If the splint is to be concave, shallow longitudinal incisions in bass-wood, then covered with adhesive plaster, will yield to allow of the bending of the splint to almost any degree of concavity. After the question of the wound has been decided by the lapse of a few days, and reaction has reached its height, the application of a plaster-bandage may be made. At first dressing, unless the case be in a hospital under constant observation, the plaster-bandage does not commend itself. If necrosis of the fragment take place, keep up free drainage and wait for its detachment. Operative measures against dead bone, while it still remains fixed, have not been satisfactory, and, again, waiting is conservatism. Only the outer portion of the bone is finally cast off, oftentimes only a thin shell; thus, by waiting, the deposits of bone under this shell become thicker and thicker, and when, finally, the shell is cast off, a firm callus has taken its place. Passive motion may be begun as soon as it can be done without disturbing the fracture. Massage, tonics, exercises, cold and hot affusions—all may be employed to restore the function. In reviewing the notes of fifty-three cases of compound fractures I have treated, there has been no case of non-union, and none of any marked disturbance of contour. There has been one death from pulmonary embolism.

In conclusion, in order to bring the subject before this Society for discussion, I would submit the following:

1. The indications for amputation in cases of compound fractures rest upon the complications; the injury of bone itself is not sufficient grounds for amputation.
2. The fragments should be thoroughly reduced, and, if necessary, held in place by means of some mechanical appliance, preferably strong silk ligatures.
3. The silk ligature may be fixed in the groove made by a saw, cut off close, and allowed to remain buried in the wound.
4. The fracture should be treated on the same principle as a simple fracture.
5. In case of infection provide for ample dependent drainage. In case of doubt treat the case as if it were known to be infected.
6. Restore the normal relations of the soft parts, if necessary, by means of buried sutures.
7. If there are ragged edges, the wound should be revised by trimming off the crushed tissues, and if the opening in the skin be soiled, continuous excision of the margin should be practised.
8. If necrosis of the bone follow, maintain free drainage and wait for a complete separation.
9. Unless under continuous observation, plaster-of-Paris bandage should not be applied until the acute symptoms have subsided and the condition of the wound has declared itself.
10. In restoring the normal function persistent treatment by massage, baths, tonics, and, possibly, electricity, are important.
11. The bone should be treated as if there was no injury to soft parts; the soft parts as if there was no injury to the bone.

380 Pearl Street, Cleveland, O.

An Epidemic of Priapism.—Dr. Meynier, a French army surgeon, has recently published a curious bit of medical experience. A company of troops *en route* having halted for some time at El Hacaiba, the men were nearly all seized with priapism and prolonged and painful erections. Considering that an absence for some time from a garrison town might be the cause, the surgeon ordered light diet and flaxseed tea. The condition, however, became steadily worse. The erections continued throughout the company, and the men began to complain of great lassitude and dryness in the throat. Finally many had marked hæmaturia. Careful investigation disclosed the real cause of the trouble. During their leisure the men had been hunting frogs at a neighboring stream. The poplar and willow trees along the banks were found to be thickly covered with coleoptera of the family of cantharides, *meloe*. Chilled in the early morning they fell by thousands into the water, where they were gladly and greedily devoured by the frogs—which later gave similar pleasure to the soldiers. The taste of the flesh was in no way injured, but its effect upon the genito-urinary system of the divers was disastrous. The removal of frogs' legs from the bill of fare put an end to the curious epidemic in a few days.—*The Boston Medical and Surgical Journal.*

Vaccination: A Study in Black and White.—A physician in Boston who has been vaccinating the employees of some of the large hotels, reports that he was able to vaccinate forty eight white persons an hour, but only thirty-eight negroes in the same time. As all the other conditions were the same, the greater thickness of the black man's skin suggested itself as the explanation.

MEDICAL RECORD:

New York, February 10, 1894.

THE NEW STATE LUNACY BILL.

THE discussion of the State Care Act for the Insane, and its autocratic interpretation by the Lunacy Commission, have cumulated in the presentation of a new bill for the abolition of the Commission, and the creation in its stead of a Committee on Lunacy, to be appointed and controlled by the State Board of Charities. This bill contains the following sensible and practical provisions:

Within ten days after the passage of this Act, the State Board of Charities shall, at a meeting called for that purpose, elect by ballot three members of its own body, who shall serve without compensation, and who shall constitute the "State Committee" of said board thereafter. At each annual meeting said board shall elect three members of said committee for the ensuing year. Said State Board of Charities shall appoint a Secretary of said Committee who shall be known and designated as the "State Commissioner in Lunacy," and who shall be a reputable physician, a citizen of this State, and a graduate of a legally chartered medical college, having been in the actual practice of his profession at least ten years, and who has competent knowledge of the treatment of the insane and the management of institutions for their care and custody; he shall receive a salary of five thousand dollars per annum, and one thousand dollars in lieu of travelling and other incidental expenses. The said committee shall elect its own chairman.

"The said Committee in Lunacy is empowered and required to execute, through itself or its secretary, all the provisions of this Act which pertain to its office, and shall direct its secretary accordingly; and shall also, with the consent of the Board, make such other rules and regulations for its own government, and that of its secretary, as are not inconsistent with the provisions of this Act; but said committee shall, at all times, be subject to the authority and control of the State Board of Charities.

"All the powers and duties conferred upon, and exercised by, the State Commission in Lunacy, in conformity with Chap. 273, Laws of 1890, and Chap. 214, Laws of 1893; or acts amendatory thereof, or by any other act not specially mentioned, or enumerated herein, are hereby transferred to, and conferred upon, the State Committee in Lunacy and its secretary, created by the first section of this Act, and the State Commission in Lunacy is hereby abolished.

"It shall be the duty of the State Commission in Lunacy to transfer to the State Committee in Lunacy, on the written request of the chairman of said Committee, all records, papers, books, office furniture, and other property of whatever name or nature, belonging to the State and in its possession.

"The said Committee shall be provided by the proper authorities with suitable accommodations in the State Capitol for its office, where it shall hold its meetings as often as once in three months, the time for such meetings being fixed by the Committee; additional meetings may be held at other times and places as the exigencies of the service may require. The Committee is authorized to employ such number of clerks as it may deem necessary, but the total cost of such service shall not exceed four thousand dollars in any one year."

This bill is the outcome of a free interchange of opinion by all those who are interested in the success of the State Care Act, and whose practical experience in the treatment of the insane in our State hospitals entitles their conclusions to respect and their recommendations to confidence.

Notwithstanding efforts on the part of such as still believe in County care to prove that the present law is a failure, and that a return must be made to the old system, the convictions of those who have given the subject careful study are firmer than ever, as to the great advantages of State care for both acute and chronic insane. The only fault has been in the objectionable and perverse methods of its administration by the Lunacy Commission as now constituted. In fact the time has come for a change, not only in the personnel of the Commission, but in such curtailment of its powers as shall make appeal from its judgment in all times and under all circumstances a possible measure.

While willing to give the Commission due credit for its efforts to carry out the law, we must admit that it has signally failed in so doing. At best the present construction of the law can only prove the danger, even to conscientiously inclined public officers, of having extraordinary power given them, and the temptation to enforce it oftentimes against the dictates of common sense or ordinary reason.

It will be seen that the proposed law has several features which are improvements on the one now in force. It is a transfer of the duties of the Commission to a Committee of the State Board of Charities, which latter has always had a supervisory control of all State charities. It consolidates functions which are now uselessly separated, thus simplifying machinery, conserving common interests, and restricting expenditure. The present Lunacy Commission costs the State nearly thirty thousand a year, while the new committee can do its work more efficiently, more harmoniously, and more consistently, for one-third of that sum. Moreover, the effectiveness of the proposed law has already been amply demonstrated in Pennsylvania, which, after a varied experience in lunacy legislation, has settled upon it as incomparably the best. While there is no intention in the new bill to alter the essential features of State control of expenditures, the advocates of the new measure are content to try the experiment of continuing the principle of such supervision under a more distributive method of its administration, and one in which there is more division of responsibility and consequently less oppor-

tunity for error by individual judgment. But above all, it very properly removes the supervision of our great State hospitals from the domain of politics, by vesting all responsibility in the State Board of Charities, composed of independent and representative citizens who make and control appointments, and whose only accountability is to the public through their reports to the Legislature. The profession throughout this State should be particularly interested in this new bill, and should use its influence in every direction to secure its passage.

A STUDY OF DREAMS.

It is a curious fact that the phenomena of dreaming, which form so interesting and conspicuous a portion of every human life, have been but little investigated in the strictly scientific and experimental method. There are plenty of dream-books and folk-lore; medical writers all allude to dreams as factors in disturbed sleep; and some curious attempts have been made to associate the character of the dreams with the pathological condition. But, after all, even the traditional association of nightmare and a heavy meal does not stand on very sound scientific footing. Miss Mary Whiton Calkins, in the *American Journal of Psychology*, has contributed something toward the filling of the lacuna in our knowledge of dreamland.

The subjects experimented upon were two in number, a man of thirty-two, and a woman of twenty-eight. The investigation was carried on for eight weeks, during which time the man had one hundred and seventy, and the woman two hundred and five dreams! They had not previously supposed themselves to be great dreamers, and the large number is accounted for by the fact that pencil and paper were kept at hand and every transient dream was at once recorded on awaking. The first point investigated was the time at which the dreams occurred. It was found that most dreams took place in the morning hours. In one case, 73.2 per cent. occurred after 4 A.M., very few on falling to sleep or before midnight. The next inquiry covered the question of the relation of the character of the dreams to the thoughts of waking life. It was found that in about fifty per cent. the character of the dream was distinctly connected with some waking thought or suggestion, while in forty per cent. some slight or vague suggestion existed.

As to the vividness of dreams, it was found that about one-half could be classed as very vivid or decidedly vivid, so that details could be recalled and a good story written. The most vivid dreams occurred after four o'clock.

A careful analysis of the dreams shows that during this condition the mind may exercise fairly normal activity. That is to say, the dreamer may remember correctly, imagine clearly, and think connectedly. The latter phenomenon, however, is rare. The statistics show that in the great majority of cases the dreams are associated with familiar persons and places. The subject-matter of the dreams was generally trivial, and the writer concludes that one seldom dreams of the serious problems and emotions that confront him while awake. In times of bereavement one seldom dreams of the dead. Miss Calkins considers it very improbable that the train of thought in dreams is swifter than in waking life. If she is right it destroys the credibility of a good many interesting anecdotes. Thus Napoleon is said to have dreamed of a journey, a siege, and a cannonading, and awoke while some explosion was still reverberating.

Curiously enough, some attention is given to the subject of prophetic dreams and of telepathy. While viewing the subject with commendable scepticism, the writer cites several dreams which appear to have a certain previsual or telepathic character. The relationship of certain diseases to dreams is a matter of especial interest to the physician; but here he must himself take up the subject and carry out investigations. We trust that Miss Calkins's article may suggest further work in more strictly medical lines.

THE MODERN EYE.

An enormous amount of statistics is accumulating regarding the modern eye and its relation to disease. It has been abundantly proven that under the influences of civilization this organ is undergoing decided change, and that often it is not at all equal to the work which it is called upon to perform. Referring only to the subject of refraction and accommodation, Roosa and Emerson have shown that only about one person in ten has an emmetropic eye; the remaining nine being hyperopic or myopic. Among the school children of Antwerp, Mets found that 2.13 per cent. were short-sighted, the percentage increasing with age and being greater in girls. In London, Stephenson found that among 1,149 children, 1.97 per cent. of the Christian, and 10.63 per cent. of the Jewish, pupils were myopic. In the German gymnasia the percentage ranges from 22 to 58. In New York the percentage ranges from 3.55 among young children to 26.8 among the adults (Loring and Derby). In Philadelphia schools the general average was 13.7 (Risley). In Chicago the myopia ranged from 4 09 to 27.08 (Smith). In our colleges the percentage ranges from 35 in the Freshman to 47 in the Senior year. Among classes whose occupation does not tax the eyes the percentage of myopia is only two or three, and the average for a civilized community may be taken to be about eight per cent. Thus it seems that the population of a civilized country starts naturally with only about two per cent. of short-sightedness, and that this increases until among some classes every other man is myopic.

The exact frequency of hyperopia is less well determined. Tscherning estimated the percentage of this error in excess of one diopter to be from two to five. Of late years much more stress has been laid upon the slight degrees of hyperopia. The frequency and importance of astigmatism are subjects which have also received especial attention of late, and it is to some statistics bearing on these points that we wish to call attention now. In an article entitled "The Modern Eye," published by Dr. W. F. Southard, of San Francisco, in the *Pacific Medical Journal*, the results of the examination of thirteen hundred eyes for hyperopia and astigmatism are given. The cases, as we understand the author, do not represent the general population, but are based upon the records of his own practice, and therefore include only persons who apply to an oculist for some refractive trouble. The figures show, therefore, the relative percentages among this class.

It appears, first of all, that the greatest amount of suf-

fering occurs between the ages of fifteen and twenty-five, when 55.23 per cent. of the whole number applied for treatment. The female sex suffers more than twice as much as the male. Among the thirteen hundred, about three-fourths had hyperopia, with or without astigmatism, while one-fourth had myopia, there being much more astigmatism with the latter condition. These figures correspond to a considerable degree with those of Dr. Gould. A further analysis shows that the most frequent refractive trouble is simple hyperopia, fifty-eight per cent.; next, astigmatism of all kinds, thirty-three per cent.; and last of all, myopia, eight per cent.

Thus, although so much more attention in the past has been devoted to myopia, it is, after all, hyperopia, with or without its attendant astigmatism, which most pesters and threatens the modern race. Myopia can be usually endured, if not cured; but hyperopia makes trouble.

THE EFFECT OF CASTRATION UPON THE SEXUAL INSTINCT.

Some years ago we excited considerable discussion over a statement, which was made editorially, to the effect that the castration of women led to a gradual extinction of their sexual feelings, and did in a sense unsex the woman. This view at the time was strongly combated by many authorities learned in oöphorectomy, and experienced in the conditions which follow it. The laws of life generally, however, are not, as we believed, different with women than with lower animals; and a longer experience has confirmed this opinion. In an article on the subject by Dr. William Goodell, a change of opinion on the part of gynecologists is indicated. In Dr. Goodell's earlier teachings he maintained that oöphorectomy after puberty did not completely unsex a woman; her capability of being impregnated was lost, but her sexual feelings remained much the same. "In this," says the *New York Medical Journal*, "he agreed with Koeberlé, who held that it caused no marked change in the condition of those that had been operated on; they were women that had abruptly reached the climacteric, but their instincts and affections remained the same, and their sexual organs continued to be excitable. A riper experience has forced Dr. Goodell to the conclusion that, in the majority of women that have been 'castrated,' the sexual impulse soon abates in intensity, much sooner than after the natural menopause, and that in many cases it wholly disappears. This corroborates the report of the special committee appointed to investigate Imlach's cases of 'castration' at the Woman's Hospital in Liverpool; they found 'a distinct loss of sexual feeling to such an extent as to cause serious domestic unhappiness in not a few instances.' Otherwise Goodell finds no marked physical or psychical change. The affections remain the same, the breasts do not flatten or wither, obesity does not ensue, neither facial nor corporeal hirsuties follow, and the tone and quality of the voice are unchanged; in other words, there is no tendency toward any characteristics of the male type."

Dr. Paul Diday, the distinguished French surgeon, died on January 9th, aged eighty-three. He was one of the founders and the first editor of the *Lyon Médical*.

THE INCOMES OF PROFESSIONAL MEN.

A writer in *The Forum* discusses the question of incomes of the professional classes in England, and comes to the conclusion that the very successful are overpaid, while the average man is meagrely paid. He gives the average income of the clergy as $600 a year, that of a barrister $1,200, and that of a medical man $1,200. A successful lawyer gets $65,000, while the income of Sir Andrew Clark is estimated at $75,000 or $100,000. This great difference between the incomes of mediocrity and that of success, he thinks is characteristic of the English social system.

There is not any American physician who earns $100,000 a year, and we doubt if $1,200 is not higher than the average medical income. Such figures, however, mean little. The average medical income, for example, varies enormously according as the figures used include the first five years in practice or not. Again, incomes vary enormously in different parts of the country, according to whether one estimates what the doctor charges and what he collects. There is said to be a margin of twenty-five or thirty per cent. between these two sums in this neighborhood. All one can say is that the industrious and God-fearing physician is seldom in want, and never in affluence.

News of the Week.

The Nurses' Bureau of the Academy of Medicine was opened on Monday, February 5, 1894. The hours are from 8 A.M. to 10 P.M. Each nurse who registers will be charged a fee of $2 a year for registry, and will be required to have an endorsement by two reputable physicians, who will be written to minutely as to their knowledge of her character and capacity as a nurse. Each time that a nurse is taken out by a patient, the patient will pay a fee of $2 to the bureau for this privilege. When a nurse leaves a case, the physician for whom she has been nursing the case will be written to for minute details as to her management of it, and in many instances the friends of the patient will also be written to. In this way the record of each nurse grows up by accretion, and if a nurse notably fails to perform her duties, she will not be permitted to have the privileges of the school. For a time it is proposed to have the rooms open from eight to ten o'clock in the morning, and certain lists of names will be left with someone in the building over night. As soon as the bureau is running fairly well, it will be kept open day and night. A telephone will be put in for the use of the bureau, and the superintendent will be a trained nurse.

Examinations for Marine Hospital Service.—A board of medical officers will meet Monday, April 16, 1894, in Washington, D. C., for the purpose of examining candidates for appointment to the grade of Assistant Surgeon, in the Marine Hospital Service. For further information address, The Supervising Surgeon-General, U. S. Marine Hospital Service, Washington, D. C.

Death of Horatio N. Buckley, M.D., of Delhi, N. Y.—Dr. Horatio N. Buckley died at Delhi, N. Y., January 23, 1894, from a complication of diseases, at the age of seventy-four. He was born at Unadilla, Otsego County,

N. Y., studied medicine at Franklin, Delaware County, graduated at the University of New York, 1845, commenced and continued the practice of his profession until his last sickness, nearly fifty years. He held all the important positions in the gift of his town and county during his life; also the posts of postmaster for sixteen years, and the position of examining surgeon for pensions for twenty years. He always enjoyed a large practice, especially in obstetrics, his attendance in such reaching very nearly 4,000. His consultation practice was large and extended. He was always faithful and constant; very seldom was he, in his long professional career, out of reach of those needing his services.

American Gynecological Society.—The next meeting of the Society will be held in Washington, on Tuesday, May 29th. According to the resolution adopted at the last meeting, the morning sessions of the first two days will be devoted to the discussion of the following subjects: 1, Extirpation of the uterus in disease of the adnexia; 2, the management of face presentations; 3, rupture of the uterus: surgical *vs.* expectant treatment. The afternoon of the third day will be devoted to a special discussion before the Congress, under the direction of the American Gynecological Society. The following topic has been assigned: "The Conservative Surgery of the Female Pelvic Organs." Referee, Dr. William M. Polk; co-referee, Dr. William Goodell. Since there will be time for only twelve or fifteen papers in addition to the above discussions, those gentlemen who desire to contribute are requested to send the titles of their papers to the Secretary on or before April 1st, as he will be compelled to limit the number to the first fifteen which he receives. The Fellows are reminded of the By-law: "All papers that may be read before the Society, and accepted for publication, shall become the property of the Society, and their publication shall be under the control of the Council. Such papers may be published in full in medical journals, provided that they are also printed in the 'Transactions.'" There are eleven vacancies in the list of Fellows.—Henry C. Coe, *Secretary.*

Hospital Quarrels.—There has been trouble in the Brooklyn Homœopathic Hospital for some time. It reached its climax recently; the visiting staff resigned, and new members were promptly appointed. There has also been a quarrel between the staff of the Eastern District Homœopathic Hospital and the managers. This ended in the same way, by the resignation of the visiting physicians.

The Prevalence of Measles.—There has been an unusual prevalence of measles in this city during the past month. The number of cases has amounted to almost one hundred daily.

The Elmira Reformatory.—The managers of this Reformatory have formally expressed their confidence in the work and policy of the superintendent, Mr. Brockway, and have placed him again in charge. They have, however, *Resolved*, That in consideration of a false sentiment just now prevalent toward the Reformatory, the disciplinary measure known as spanking, which has been suspended during the incumbency of the acting General Superintendent, be only resumed upon the formal order of the Board of Managers.

A Georgia Physician Found Guilty of Murder.—Dr. J. B. Hinkle, of Americus, Ga., who for many years was Speaker Crisp's family physician, was recently found guilty of murder. A year ago the doctor and his son, who is also a physician, shot and killed a professional rival, Dr. Worsham. Between the men there had been a feud of years. The trial has been regarded as one of the most noted in Georgia. Dr. Hinkle's son will be placed on trial for the same offence.

Our State and City Charities Cost $7,468,819 annually, other benevolent institutions cost $14,939,163, making a total of over twenty millions for charitable, correctional, and reformatory purposes. The total number of the submerged class was 80,543. During the ten years between 1883 and 1893 the expenditures have doubled, showing a ratio of increase nearly four times greater than that of the State's population. The Board thinks that much of this increase in the insane, as well as the increase in pauperism, in the State, comes from the greatly increased immigration from central and southern European countries, many of them weak and defective, with tendencies to insanity. The Board urges the establishment of a colony for epileptics, and repeats its recommendation of last year that a new reformatory for men be established near New York and Brooklyn.

Reception to Surgeon-General George M. Sternberg, U. S. Army.—Mr. William H. S. Wood gave a reception on Tuesday evening, at his residence in East Sixty third Street, to Surgeon-General Sternberg, U. S. Army. A large number of prominent physicians of this and other cities were present to do honor to the occasion. Medical officers of the army and navy, as well as a full representation of distinguished citizens, also helped to swell the list of those who paid their respects to the distinguished guest. Altogether it was the largest and most successful medical reception of the season.

Physicians and the Income Tax.—Dr. W. P. Whery, of Fort Wayne, sends the following interesting letter to the *Journal of the American Medical Association.* Dr. Whery seems to think that the exemption of small incomes from taxation is not unjust; but the minimum of $4,000 is by no means small. In Germany and England the tax is carried down so low as to include domestic servants' wages. This is overdoing it. Dr. Whery says: "The determination of Congress to adopt the income tax as a source of revenue calls for some remarks on its application to practitioners of medicine. It is to be noted that there are no exemptions in the bill in favor of certain methods of earning a living, but that all incomes, no matter how created, are lumped together. Justice would seem to require a distinction to be made between certain and permanent incomes and those which are precarious. Some incomes result from investments, and require no expenditure of work or money to earn them, on the part of those by whom they are enjoyed. Others are derived through personal services rendered to employers or the public, and perhaps inadequately paid for. Some incomes are not diminished by the temporary illness or absence from duty of their earner, while others are immediately arrested when they are even for an hour off duty. The President may go fishing for a week, and his *per diem* is paid as punctually as if he were at work in his office. But a medical man takes a holiday or occupies a sick-bed

only by paying a penal fine for the privilege. Nevertheless, the bill treats both incomes alike. The exemption of small incomes from the tax is not unjust, inasmuch as a minimum living income should be exempted, and also because small incomes are generally precarious and earned by personal services. But a medical man's personal service is even more disadvantageous than that of a mechanic working for wages in a factory. The latter is sure of pay for every hour he works; the doctor has all the risk of collecting his dues. Again, if the mechanic falls ill, his wages stop; but, on recovery, he resumes his income as before his illness. The medical man falling ill loses his income during his incapacity, and further loses many patients, who used to treat with him regularly, to some other doctors. He not only suffers loss of a portion of his income for the work that he was unable to do, but breaks up his business to a certain extent also. Hence the physician is in a worse plight as a payer of income tax than even a mechanic. The bill, to be just, should make a distinction between precarious and permanent incomes; and a special exemption should be granted medical practitioners on account of the risks that their earnings are subject to, beyond those of any other members of the community. Certainly, in returning an estimate of income a physician should be entitled to deduct so many days for necessary recuperation and illness; he should make another deduction for the difficulty of collecting his fees, which all State laws seem to increase; and he should make a further deduction for the extra cost over lawyers, ministers, office-holders, clerks, and mechanics which he has to incur in carrying on his business. It is a well-known fact that doctors who seem very prosperous have to expend almost up to the margin of their earnings to keep up their business. This is a subject for the county societies to discuss, and, if possible, take action upon."

A Bill to Establish a Department of Public Health.—Dr. C. E. Comegys, Chairman of the Committee of the American Medical Association, reports a bill recommended by the Committee. It provides "That there shall be established a Department of Public Health. There shall be appointed by the President from the medical profession, by, and with the advice and consent of the Senate, a Secretary of Public Health, who shall be intrusted with the management of the department herein established. He shall be paid an annual salary of $8,000. There shall be appointed by the President, with the approval of the Senate, an Assistant Secretary of Public Health, at an annual salary of $5,000. The Secretary of Public Health shall, with the approval of the President, provide suitable offices for the department, and shall employ such assistants and clerks as may be necessary. The rest of the bill provides for collecting and investigating sanitary questions of all kinds, and making weekly and annual reports. No executive authority is conferred in matters of quarantine. The department would have ample power to investigate public health problems.

Proposed Changes at Jefferson Medical College.—At a recent annual meeting of the Philadelphia Alumni of Jefferson College, a resolution was unanimously adopted requesting the Board of Trustees to appoint a member of the Faculty, Provost of the institution, so as to give it a responsible chief executive officer. Reorganization was also advocated by abolishing the present fee-system of the chairs, and substituting therefor a fixed salary to each member of the Faculty.

Legislation to Prevent Blindness.—At the last meeting of the American Medical Association, the Section on Ophthalmology passed the following resolution:

Whereas, There are in the United States several thousand persons who have become blind because of ophthalmia neonatorum, and,

Whereas, This unfortunate result is largely preventable, being due to the neglect of nurses and midwives, Therefore,

Resolved, That it is the sense of this section of the American Medical Association, that a committee of five be appointed by the chair to urge in all parts of the country, by personal application, by circulars to physicians and legislators, and by blank forms of a desirable law, such legislation as will tend to lessen the blindness caused by this disease.

A committee, consisting of Drs. Lucien Howe, Henry Gradle, George M. Gould, James L. Thompson and G. C. Savage was appointed, and are working to interest the profession in securing the passage of the following law:

"The people of the State of.....represented in Senate and Assembly, do enact as follows:

"*Section* I. Should one or both eyes of an infant become inflamed, or swollen, or reddened at any time within two weeks after its birth, it shall be the duty of the midwife or nurse having charge of such infant, to report in writing, within six hours, to the health officer, or some legally qualified practitioner of the city, town, or district in which the parents of the infant reside, the fact that such inflammation, or swelling, or redness of the eyes exists.

"*Section* II. Any failure to comply with the provisions of this act shall be punished by a fine not to exceed two hundred dollars, or imprisonment not to exceed six months, or both.

"*Section* III. This act shall take effect on the..... day of.....eighteen hundred and ninety....."

Fighting a Telephone Monopoly.—The Kings County Medical Society and the Brooklyn druggists are fighting the New York and New Jersey Telephone Company. The telephone company recently called the attention of the physicians and druggists to a clause of their contracts prohibiting any person except a subscriber using the telephone, unless a fee of ten cents is paid for every message. A patient cannot call up his physician unless he pays the customary fee. Druggists, physicians, and patrons are indignant at this action of the telephone company.

The Effects of Medical Legislation.—At the last meeting of the State Board of Medical Examiners of the State of Washington, held in Seattle, there were twenty two applications for a license to practise, of whom twelve failed to pass the required examination and were rejected. The Board now requires a general average of seventy-five per cent. on all branches, a rise from its former standard, and soon the standard will be raised to eighty per cent.

Heubner, of Leipzig, has been elected the successor of Henoch in the chair of pediatry at Berlin.

Medical Senators.—The recent elections to the French Senate have resulted in the return of several members of the medical profession, among whom are Professor Cornil, Dr. Velten (Bouches du Rhône), Dr. Dellestable (formerly deputy for la Corrèze), Dr. Pitti-Ferrandi (President of the Syndicate of Bastia), and Dr. Gérente (Algiers).

"The Grand Old Man" of Medicine.—The *Medical Press and Circular* gives a new title to the Autocrat of the Breakfast Table in the following bit of news. It would lead its readers, however, to infer by analogy that Sir Spencer Wells had written the poems of Thomas Hood. "The 'Grand Old Man' of Medicine seems to be Dr. Oliver Wendell Holmes. The College Club, of Boston, recently gave a reception in his honor, and about five hundred persons were presented to him. He received them as he sat 'in a laurel-decorated chair under a bower of palms.' During the course of the proceedings Dr. Holmes recited 'The Last Leaf,' 'Dorothy Q.,' and 'The Chambered Nautilus,' all of which must have been intently listened to. Truly, we have no one in this country, of similar standing belonging to the profession, who could perform such a feat. Fancy Sir Spencer Wells, for example, reciting 'The Dream of Eugene Aram' at the *conversazione* of the Medical Society!"

Vaccination in Vermont.—The State Board of Health of Vermont, at its meeting in Burlington last week, voted to recommend a general vaccination throughout the State, in consequence of the prevalence of small-pox in Boston and New York, and the signs of scattered infection in other New England places.

The Testimony of the Physician Regarding his Patient.—The policy of the law is to make the relation of physician and patient confidential and sacred. Only the patient himself, or, in case of his death, his legal representative, may waive the seal of secrecy and confidence. Thus holds the Supreme Court of Indiana, in the case of Gurley *v.* Park, decided November 23, 1893. The application given to this doctrine here is to the effect that in a case where there is no legal representative, as administrator or executor of a deceased person to make waiver, the physician who attended her cannot testify in an action to set aside her will as to her mental condition at the time she made the will, he being present in his professional capacity. The law, this court says, forbids the physician from disclosing what he learns in the sick room, no matter by what method he acquires his knowledge.—*Journal of the American Medical Association.*

Mother's Milk not Sterile.—Few things can be regarded as being quite pure and untainted nowadays, and our readers will not be surprised to hear that mother's milk must be numbered with the majority. Honigmann finds that human milk obtained with all antiseptic precautions from seventy-three breasts of sixty-four nursing women was only sterile when duly cultivated in four cases. In the remainder staphylococcus albus was present, and in forty-four cases the staphylococcus aureus; while in three instances other bacteria, a bacillus, and a sarcina were found. The number of germs varied from one to upward of 9,000 in a cubic millimetre. These observations are of interest in reference to the occurrence of thrush in children, to the origin of which they may furnish a clew, and also to the liability that children while still suckling present to suppuration after wounds accidentally or intentionally inflicted.—*The Lancet.*

Dr. Pascal.—M. Zola is a great artist, no doubt, but he doesn't know science, or, least of all, medicine. His Dr. Pascal is a quack, a humbug, a ridiculous thing. He utters no original thought, and his wonderful scientific investigations are not science but silly nightmares. M. Zola should try romance. He has a genius for literary expression, but no capacity to appreciate the character and work of a true *savant*. This is what a physician feels who reads his book.

Quarantine Hospitals for Dogs.—The *Medical Review* advocates the establishment of quarantine hospitals for dogs suspected of hydrophobia. The Health Department might easily arrange for such a place. But who will be the official dog-catchers for suspected mad dogs?

Obituary.

PROFESSOR THEODORE BILLROTH,

VIENNA, AUSTRIA.

Professor Theodore Billroth, the famous German surgeon, died February 6th, of heart disease, aged sixty-five, at Abbazia, a well-known Austrian winter resort, where he had gone to recruit his failing health.

He was born at Bergen, Rugen Island, April 26, 1829, and studied medicine in the Universities of Gottingen, of Berlin, and of Vienna. He became an assistant at the surgical clinic of the University of Berlin, and privatdocent in 1856. In 1859 he was professor of surgery and chief of clinic, at Zurich. In 1867 he fulfilled the same functions at Vienna. In 1870 he was a director of the military hospitals on the Rhine. In 1881 he successfully performed his first operation of pylorectomy for cancer of the stomach.

This feat gave him a world-wide reputation as a skilful surgeon, and enabled him to take a leading position as a daring and successful operator. Indeed, for many years past he has been considered the first surgeon in Europe. His clinics became famous throughout the scientific world for the number and character of the operations performed by him, and students from all parts of the world were eager witnesses to his wonderful surgical dexterity. His counsel was eagerly sought in the different capitals of Europe and Asia, and even in Egypt, and he worthily represented the advanced thought and practice of his day and art. Although called everywhere in consultation, he seemed to have an aversion for handling comparatively unimportant cases simply for the sake of money-making.

Nor did he care for such honors as were coveted by many of his *confrères*. Ten years ago, Emperor Francis Joseph made him a member of the highest legislative body. He also had decorations almost without end—Turkish, Russian, German, Austrian, and others.

Of his family he preferred the companionship of his eldest daughter, who was unmarried. It used to be remarked in Vienna, that they seemed to be more like brother and sister than like father and daughter. He left a widow and three daughters.

In appearance he was a little above the medium height and of rather heavy build. He had a pensive look as he walked, stooping slightly and with head bent forward. He had small blue eyes, and was of an easy-going disposition.

During the last months of his life he suffered from debility due to his heart trouble, but death finally came to him suddenly and peacefully.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-eighth Annual Meeting, held at Albany, February 6, 7, and 8, 1894.

HERMAN BENDELL, M.D., PRESIDENT, IN THE CHAIR.

FIRST DAY, TUESDAY, FEBRUARY 6TH—MORNING SESSION.

President's Inaugural Address.—DR. BENDELL, in his inaugural address, mentioned the fact that under the influence of the recent laws the number of illegal practitioners was constantly on the decrease, and the standard of usefulness of the profession had constantly risen. The work of the Society was being appreciated by the people. The membership of the Society was proportioned from districts according to the number of members of the Assembly, and under the new apportionment some districts had a decreased membership. The President, therefore, suggested that presidents of county societies be made, during their terms of office, *ex-officio* members of the State Society, without, however, the right to become permanent members.

During the year 327 candidates had appeared before the State Board of Examiners; 267 were successful; 17 were homœopaths, 6 eclectics, and 244 regulars. It had been suggested that the examinations be divided and that the first be for primary branches and occur during the college year.

Mention was made of the success of the Pan-American Medical Congress; donations were requested for the State Medical Library; the advisability of holding alternate or third meetings of the State Medical Society at some other place than Albany was suggested, and approval of the Public Health Bill proposed by the New York Academy of Medicine was recommended. The list of deaths for the year had been considerable. Special regrets were expressed for the loss of Dr. Laurence Johnson.

On motion the address was referred to a special committee. DR. BENDELL appointed Drs. W. W. Potter, L. S. Pilcher, Heaton, and Brush as such committee.

Communication from the Board of the Regents.—Acting on suggestions from physicians of prominence, the State Board of Regents had voted that hereafter it was inexpedient for the Board to confer the honorary degree on persons nominated by different State societies, as had been the custom.

Resolution to Nominate in Open Meeting Withdrawn.—DR. A. JACOBI, who had given notice at the last meeting that he would offer an amendment, to make nominations for president and vice-president in open meeting, said he had done so to draw out what arguments might exist in favor of or against such a change. The arguments offered had been almost altogether against, the two principal ones being that too much time would be taken from the scientific work, and that the large number of delegates from Brooklyn and New York would have practically control of the election. He therefore wished to withdraw the proposed amendment. No objection was made.

Against Central Management of Institutions for the Insane.—DR. EUGENE BEACH, of Gloversville, offered the following, which was adopted:

Whereas, The institutions established by the State for the care and treatment of the insane are an abiding evidence of the progress of medicine and of the medical profession's enlightened conception of the needs of the insane; and,

Whereas, They are distinctly medical institutions which should remain in the future, as in the past, under immediate medical direction and control; therefore,

Resolved, That recent attempts to place the State Hospitals for the Insane under centralized management constitute a distinct menace to the interests of the insane, and that this Society deprecates and deplores any policy that is calculated to inject into the great charitable institutions of the State the dangerous element of politics—always subversive of the scientific welfare of such institutions, and that it recommends that the Legislature take such action during its present session as will emphasize the medical character of the State institutions for the insane, and tend to the restoration of local medical control, subject to proper State supervision, as against the assumption of all executive authority by a centralized power.

Resolved, That the Committee on Legislation be requested to take such action as they may deem necessary in obtaining legislation in conformity with the desiderata herewith declared.

Coroner Resolutions of Academy of Medicine.—DR. A. JACOBI read the resolutions which had been adopted by the New York Academy of Medicine, relating to a change in the coroner system, and on motion the Society approved of the same.

Committee to Name State Examiners.—The President named as special committee to nominate candidates for State Medical Examiners, to be selected from the Board of Regents, Drs. Roosa, Jacobi, Vander Veer, Suiter, and Sherman.

DR. L. S. PILCHER moved that the nomination of this committee be placed in the hands of the Nominating Committee.

The PRESIDENT said he had made the nominations under a standing rule.

DR. PILCHER appealed from the ruling, claiming that a previous session could not make rules governing the present one except through a by-law. After some discussion Dr. Pilcher was permitted to withdraw his appeal from the President's ruling.

DR. SAMUEL WARD, of Albany, moved as an amendment to the by-laws, that the appointing of this committee be placed in the hands of the President of the Society. In referring the proposed amendment, as usual, to the Committee on By-laws, the committee was instructed to report at the present session.

The committee appointed, however, stands for the present year.

Incidentally the question was raised whether the committee appointed to recommend members for the State Board of Examiners should submit their report to the Society, and the President ruled that the report should be made to the Society, and that the Society had the power to amend or approve the report entire.

Hemorrhagic Serous Effusion of the Pleura, with Report of a Unique Case.—DR. W. S. CHEESMAN, of Auburn, read the paper. The case reported occurred in a woman without hemorrhagic diathesis or known cause. There were, however, uterine fibroids. From January to July, 1891, he aspirated the right pleural cavity over a dozen times for hemorrhagic effusion. There was no evidence of adhesive inflammation. As the patient was also having hemorrhages from the uterus every two weeks, she became anæmic, and he carried out the idea of injecting an agent which would excite adhesive inflammation in the pleura. Iodine was employed, and, after two or more repetitions, succeeded, and the patient ceased to have further trouble on the right side. Later, however, hemorrhages occurred for the first time in the left pleural cavity, and the same treatment was carried out here, with like successful result. Now the patient was having similar recurrences of hemorrhage into the peritoneal cavity. The only like case and treatment, as far as he knew, had been reported by Dr. J. G. Heineman.

Manifestly an inflammatory effusion would not account for the condition.

DR. ELY, of Rochester, who had seen the patient before Dr. Cheesman, had made an unfavorable prognosis on the supposition that the hemorrhage was from cancerous growth in the pleura. In all he had made forty-nine aspirations, thirty-six of the pleura, thirteen of the

peritoneum. Aspirations of the peritoneum may have to go on indefinitely. In general the patient's health is good.

Dr. Ford thought the explanation of the hemorrhages was from pressure of the uterine fibroids. He knew of one case of hemorrhage into the peritoneum, and of one into the pleura, cured by removal of uterine fibroids.

Dr. Cheesman said Mr. Tait had reported two cases; in one there was hemorrhage into the peritoneum followed by hemorrhage into the pleura, in a patient having uterine fibroids.

Dr Ely could not understand how uterine fibroids could cause hemorrhage into the pleura, whatever they might do by the peritoneum.

Researches on the Eliminating Power of Diseases, and the Relation between Vaccine and Enteric Fever.—Dr William Finder, of Troy, read the paper. It was generally supposed that an attack of variola protected for life. His experience had taught him that this was true only where the person subsequently remained free from enteric and malarial fever. Enteric fever, particularly after variola, eliminated the protective power against variola. He had known patients to have variola a second time, after enteric fever following the first attack; that vaccination usually was successful after enteric fever, both in persons who had had variola and those who had been previously vaccinated. Of the latter he had had one hundred and three cases.

Dr. Seymour had had an attack of small-pox, subsequently an attack of enteric fever, but vaccination would not take in his case; nor had he had a second attack of variola, although frequently exposed.

Pneumonia in the Aged.—Dr. John H. Pryor, of Buffalo, read this paper. The distinguishing characteristics of pneumonia in the aged were its latent development, obscurity of symptoms, and its course. The temperature should be taken in the rectum, and thus taken, had, in his experience, always been elevated, usually not above 103° F. Characteristic sputa were seldom present, they never became purulent in the stage of resolution. Pleurisy was absent. The mental faculties were almost always perturbed. Recovery was marked by somewhat lengthened crisis. Physical examination was not simple in these cases for the young practitioner. The physical signs offered little information until the exudate had filled the lung to a considerable extent. Rectal temperature was never absent, and at times was the only indication of acute disease in the aged. The diseases which simulated pneumonia in the aged were hypostatic congestion, simple congestion, œdema, pleurisy, and tubercular infiltration.

The paper was discussed by Drs. Jacobi, Ely, and Elsner, who, it seemed, had seen cases run an afebrile or almost afebrile course.

Diagnosis and Nomenclature of Fevers.—Dr. Nelson G. Richmond, of Fredonia, read his second paper on this subject. The class of cases described by the author had been variously classed as remittent fever, typhoid fever, bilious fever, etc. The question of importance was to determine whether they were or were not typhoid, and whether they were or were not malarial He believed they were neither, that they were due to disturbance in the duodenum attended by toxic absorption. He had seen nearly forty cases, all recovering. The condition had lasted twenty-one to thirty-five days. The temperature had risen gradually, seldom went above 103°, and gradually went away. There was preceding constipation. The patient took matters easily, regarding the disease as an easy one. There was no sordes, no rose-colored spots, little abdominal tenderness, seldom diarrhœa; the skin was usually in color, sometimes jaundiced; the patient became emaciated as in typhoid.

The discussion was participated in by Drs. Mallory and Jacobi, who thought, before excluding typhoid or malaria, one should make bacteriological examination of the passages, of the blood, and use Ehrich's test. The mild course of the disease would not exclude typhoid.

Dr. Richmond said bacteriological examinations had not been made.

The Therapeutics of Oxygen.—Dr. Arnold W. Catlin, of Brooklyn, read this paper. His purpose was to show from experience that oxygen was a distinctly remedial agent, that it had definite work to do, and that when employed with the same judgment as other remedies, it would give the most gratifying results. Oxygen was the most satisfactory stimulant, but it was more than a stimulant, it was a food. In profound shock or hemorrhage it helped tide over life until there was time for vital repair, which latter it also promoted. Heretofore its effects upon the lungs alone had been considered, but this was a narrow view of its action and beneficial results. Oxygen was a nourisher and promoter of power to appropriate material to rebuilding the system. The author made special mention of oxygen inhalation in pneumonia and bronchitis, advocating its early and continued use. He insisted that in all conditions of the lungs in which oxygen was indicated at all, its prompt use was called for.

Discussion on Diphtheria.—This discussion had been arranged by Dr. Suiter.

The Pathology of Diphtheria—Status Præsens.—Dr. T. E. Satterthwaite, of New York, opened the discussion on diphtheria with a paper bearing the above title. In this country, pathology is understood to include pathological anatomy and pathogenesis, while the latter includes the causation of disease. Fortunately the pathological anatomy of diphtheria forms little ground for difference of opinion, it has been well studied. But the pathogeny, and with it the etiology, is still under discussion. Dr. Satterthwaite premised by saying that the evidence at hand is to the effect that the bacillus known as the Loeffler bacillus is the cause of true, genuine, or primary diphtheria. There is also a false diphtheria, to which he gave the name of diphtheroid, in which the diseased tissues have a bacillus similar in appearance, though without the pathogenetic qualities of the Loeffler bacilli. Diphtheria is therefore a contagious disease, the bacilli retaining their virulence in a remarkable manner. They generate also a soluble material which has virulent properties; while finally another soluble substance, known as anti-toxine, can be extracted from the blood of convalescents and immune animals, which may be regarded not only as protective, but also as a curative agent.

With reference to pathological anatomy, he said the presence of membrane did not indicate diphtheria, for a pathogenic diphtheritic inflammation might attack a mucous surface—the conjunctiva, for example—but still the patient have no diphtheria. The terms diphtheritic and croupous, as used by the Germans, were conventional terms, having reference mostly to the depth to which the membrane was attacked. While the membrane was characteristic, it was not an essential characteristic. The exudation was usually fibrous.

In reference to pathogeny, he reviewed the subject from his own studies in 1874–75, stating that the disease was at first thought to be due to a spherical microphyte. About ten years ago Loeffler called attention to his bacillus. This was described in the paper. Practical bacteriologists differed as to the importance of the three tests. Earlier investigations did not confirm Loeffler's statements, latterly they have done so. The bacillus had been found by different men in from thirty-four to ninety-five per cent. of cases of diphtheria. It was at first held that it did not penetrate the tissues, but during the past year this view had been overthrown. Howard, of Baltimore, had found it in great numbers in a case of ulcerative endocarditis which was diphtheritic.

Other microphytes were connected with diphtheria, especially the pyogenic streptococci and staphylococci, and there was an impression in some quarters that they alone, or in conjunction with attenuated bacilli, would produce a virulent form of diphtheria.

As to the non-pathogenic bacillus, abroad this had been found very frequently. French observers had found it in from thirty-three to fifty nine per cent. of appar-

ently healthy cases, and in seventy-one per cent. of cases of measles. American observers, however, have not confirmed these experiences, so that in this country at least it is not a disturbing factor in diagnosis. When cultivated, this bacillus differed in degree rather than in kind, but in inoculations on animals produced no result unless there is admixture of other pathogenic organisms.

Regarding tox-albumin, its toxic power was slight when the culture was acid, virulent when alkaline. The next step was that made by Behring, assistant in Koch's laboratory, who, in 1891–92, found in immune animals a something non-bacterial which neutralized the toxic products of the Loeffler bacillus. What was it? Behring believed it was the blood serum. Efforts were now being made by Behring to concentrate this serum.

There was diversity of opinion as to whether physicians should make cultures or inoculate animals for the purpose of diagnosis. Among bacteriologists it was thought this work should be done by experienced men in order to be of value. Boards of health should not attempt to make such experiments compulsory on the physician. He advocated giving every opportunity to have these researches carried out, but argued that if we were to have the best results in the shortest time we should see that the material only fell into competent hands.

Observations on the Diagnosis and Some Sanitary Aspects of Diphtheria.—Dr. A. Walter Suiter read this paper, which contained the following deductions: 1, That the Loeffler bacillus has been established beyond controversy as the pathogenic germ of true diphtheria; 2, that this had led to the classification, diphtheria and pseudo-diphtheria; 3, that it could be readily demonstrated that at least fifty per cent. of all cases clinically diagnosticated as diphtheria were not the true disease; 4, that a certain diagnosis could not be made microscopically or clinically, a bacteriological and microscopical examination being required; 5, that it was practically impossible for the general practitioner to diagnosticate the disease without laboratory facilities; 6, in view of the latter fact, where there were no facilities through local boards of health, the State Board of Health should undertake the diagnosis in all cases of slightest doubt; 7, that district laboratories should be maintained in various parts of the State, located with special regard to convenience of transportation and telegraphic and telephonic communication, so that the general practitioner might, through them, have a diagnosis within twenty-four hours. The Legislature at present was appropriating a ridiculously small amount to the State Board of Health, so that such an undertaking, of course, was beyond possibility, but a movement should be organized to have that appropriation increased.

Croup and Diphtheria — Unity or Quality.—Dr. William H. Daly, of Pittsburg, Pa., expressed belief in a paper in a single cause for diphtheria and croup, the chemical action of that cause, however, being modified by the varying powers of resistance on the part of the tissues affected. It was a toxic or albuminous development in the history of the Loeffler bacillus and presence of staphylococcus and streptococcus. Calomel and various other antiseptics now in successful use were recommended, but especially the former.

The Comparative Status of Intubation of the Larynx.—Dr. Joseph O'Dwyer, of New York, sent the paper. Conclusions from limited experience were the basis on which this procedure had been overestimated by some, and hastily condemned by others. Croup claimed more than half its victims. The word meant more than obstruction to the larynx, a fact which made treatment not at all simple. Extension of the disease to the bronchial tubes was the cause of the great mortality in spite of surgery. This was especially the explanation of the small number of recoveries after tracheotomy secondary to intubation. The percentage of recoveries in Europe had been considerably larger after intubation than in this country, a fact partly to be explained by another one, namely, that in Europe nearly all cases were treated with hospital facilities, in this country without, or in private practice. The life saving value of intubation as compared with tracheotomy was to be determined, not as much by the intrinsic worth of the two methods as by the fact that the former was permitted by all classes with little if any protest, while very few would consent to the cutting procedure, and then later in the disease. This point had been very strongly brought out as showing the far greater life-saving value of intubation in Brooklyn.

Complicated Intubation of the Larynx.—Dr. William Hailer, of Albany, read an interesting case of this kind in which the patient recovered.

Afternoon Session.

Nominating Committee.—The Nominating Committee was announced by districts in the following order: Drs. W. J. Morton, Hasbrook, O'Leary, J. E. Verdit, J. H. Glass, H. D. Wey, A. L. Bien, W. S. Ely, W. S. Zimmer; Member at large, Dr. W. H. Bailey, of Albany. Later, Dr. W. F. Cheesman was announced as member from the seventh district.

The discussion on diphtheria was then continued.

The Local Treatment of Diphtheria.—Dr. A. Jacobi read a paper on local treatment in which he strongly deprecated any local application through the mouth which would cause the child to struggle, as in more than one instance it had caused the death of the little patient, whose system had been overwhelmed and exhausted by the poison. Any injury done the mucous membrane in attempts to apply caustics or other agents would also start a new focus of diphtheritic deposit. Gargles did little good except keep the mouth clean, as they did not reach back farther than the pillars of the fauces.

Certain medicines given frequently in small doses would come in contact with the membrane and act upon it, such as mild dilution of tincture of chloride of iron, lime-water, boracic acid, or bichloride of mercury. The latter was much employed by him, 1 to 6,000 or 1 to 8,000. Disinfection of the nostrils was especially indicated, and fluid introduced by a spoon would also come in contact with the pharynx. The nasal spray was of little value. The injections should be made in the recumbent posture. Do not take the child out of bed or it might die of heart-failure. He preferred bichloride again, 1 to 10,000. Dr. Jacobi also mentioned such indications for treatment as sepsis, heart-failure, paralysis of muscles, etc.

The General Treatment of Diphtheria.—Dr. E. H. Brush, of Mount Vernon, in discussing the general treatment, expressed the opinion that many methods which had prevailed from time to time, had done actual harm, especially when carried out in a heroic manner, as was too often done. He believed the reckless and injudicious use of bichloride of mercury had actually increased the mortality, or, at most, had not diminished it. In looking over the list of recent drugs one would suppose the only indication was for antiseptics.

Dr. Brush thought the first indication was to empty the intestinal canal, which he would do by a full dose of calomel, afterward a copious injection of water might be made. The latter would also reduce the temperature if anything would. Another indication was to keep up nutrition, which called for careful attention to food. Among medicinal remedies Dr. Brush advocated free use of tincture of chloride of iron, the efficacy of which was increased by combining with it a small amount of chlorate of potash. In toxæmia, alcohol should be given freely, and if it were rejected in all forms, turpentine might be substituted. Avoid new and loudly heralded remedies.

The Use of Tartar Emetic in Diphtheria.—Dr. H. De V. Pratt, of Elmira, had had under former methods of treatment of diphtheria a mortality of thirty-five per cent., only about four per cent. under that by tartar emetic.

His plan was to give during the first twenty-four hours

one-thirtieth of a grain of tartar emetic, in frequent divided doses, the next twenty-four hours one fifteenth of a grain, afterward one tenth of a grain daily. A little opium might be added. The tartar emetic did not depress the heart or vital forces, did not interfere with appetite or digestion. The day after commencing this treatment the membrane ceased to spread, then gradually disappeared, toxic symptoms diminished; no paralysis had been seen after this treatment.

Dr. Pratt had treated forty seven cases of true diphtheria by the tartar-emetic method, the cases having been of all grades of severity. Only two had died.

Dr. A. Jacobi emphasized the value of small and frequent doses of bichloride in spite of the criticisms of Dr. Brush. He also said Dr. Pratt's explanation of the action of tartar emetic, its special action upon the mucous membrane of the throat, was that which had been claimed some years ago for the pilocarpine treatment, but the latter had been discarded.

Dr. Wood spoke of the value of peroxide of hydrogen, Dr. H. R. Hopkins of the introduction of alcohol per rectum in those who could not swallow, Dr. Seymour hoped the Society would take no action on the suggestion made by Dr. Suiter to have the State Board of Health establish district laboratories. Some further discussion took place.

Treatment of Depressions in the Skull of the Newborn.—Dr. D. D. Jennings, of New York, read the paper (see p. 166).

It was discussed by Drs. Currier, Cole, and Phelps, of New York, and Hailer, of Albany.

Senile Endometritis.—Dr. A. J. C. Skene sent the paper, which was read by Dr. Buckmaster. It was generally supposed that endometritis ceased at the turn of life. Dr. Skeene had found this not true in a number of cases, and that in other cases endometritis developed after the menopause. It was quite different from the endometritis of earlier life. It might be limited to the cervix alone, but, as a rule, involved the entire mucosa. The discharge was usually suppurative, there was atrophy of the muscular structure, which led to inversion of the mucous membrane, and gave it a peculiar appearance. Laceration of the cervix frequently accompanied the condition, and in treatment by rapid dilatation was liable to occur if it had not been present. Stricture of the cervix was frequently present, and in that event there was liable to be alternate accumulation and discharge.

Inattention to cleanliness was an important cause. A chief feature in the treatment was cleanliness, drainage, and disinfection. Iodoform was one of the most valuable agents. Among other agents, peroxide of hydrogen was mentioned. Simpler measures failing, especially where there was prolapsus, hysterectomy was to be considered.

Treatment of Endometritis.—Dr. Herman E. Hayd, of Buffalo, read the paper. In brief, the author advocated cleansing out the uterus by curettement and drainage.

Discussion on the papers was participated in by Drs. Willis E. Ford, Hayd, and Buckmaster. The latter thought hysterectomy would come to be an indication in the treatment of senile endometritis with prolapsus.

Discussion on Menstruation and Its Abnormalities.—This discussion had been arranged by Dr. A. F. Currier, of New York, who read a paper on the normal function. At its conclusion he pointed out as the duty of the family physician to instruct women with regard to care before, during, and after the period, and to see that many errors committed by girls and women should not continue without protest.

Dysmenorrhœa, its Causes and Treatment.—Dr. Howard Kelly, of Baltimore, read a paper with this title. Names often hindered arrival at knowledge of the true condition. Many physicians having made the diagnosis of dysmenorrhœa, treated it as an entity, when a knowledge of the pathology of the case might have led to removal of the cause, and saving of life. Dysmenorrhœa was nothing but a pelvic pain associated with menstrual congestion and flow, and was a concomitant of a wide variety of diseases of the uterus, tubes, and ovaries. It was merely an awkward name for a symptom of many common diseases, and should never be entered upon the history-sheet as the diagnosis of the case. In an analysis of 400 cases in which he had opened the abdomen for pelvic disease, of the 400, 291 suffered from dysmenorrhœa, 109 had none. Out of 238 of the number having minor pelvic disease 168 had dysmenorrhœa, 70 had not. Many of these women had been treated for months or years for dysmenorrhœa.

The use of morphia for dysmenorrhœa was strongly condemned. It was only justified where there was gross pelvic condition, and the patient was undergoing preparation for operation to remove the cause. Beware of beginning local treatment in young women. Try hip-baths, etc. If the dysmenorrhœa persist in any case, make thorough examination, in the unmarried per rectum.

Profuse Menstruation.—Dr. Charles P. Noble, of Philadelphia, read the paper. There were two classes of cases, those due to general or constitutional causes and local causes. Menorrhagia in young girls was usually functional, with disturbance of the vaso-motor nervous system or relaxation of tissues accompanying rapid growth. It was usually curable by general treatment. Menorrhagia arising from parturition, retained products, displacements, subinvolution, inflammation of the tubes, usually could be cured by local treatment. Menorrhagia in women approaching the menopause was usually due to gross disease of the uterus, such as fibroids, polypi, or malignant disease. An operation was called for.

Scanty Menstruation.—Dr. Franklin Townsend, of Albany, read the paper. The common cause of scanty menstruation was chloranæmia. Important influences were confinement in school, not sufficient physical liberty, mal nutrition. The treatment need only be directed intelligently and persistently.

Irregular Menstruation.—Dr. E. W. Cushing, of Boston, Mass., read this paper. As the subject was limited in such a way that he could not treat of profuse or of scanty menstruation the writer was confined to the diagnosis between irregular menstrual flow and other vaginal bloody discharges usually supposed to be menstrual. He laid especial emphasis on the necessity of making an accurate diagnosis in all cases, and went over the various diseases which might cause hemorrhages at the menstrual period or at other times. These included extrauterine pregnancy, inflammatory affections of the tubes and ovaries, fungous endometritis, polyps, subinvolution, fibroma uteri, ovarian tumors, uterine adenoma, carcinoma, etc.

The writer also called attention to the various general diseases which may disarrange the menstruation, such as sorrow, homesickness, phthisis, and other wasting diseases on the one hand, and heart disease, violent emotions, sexual excitement, etc., on the other.

Again, in conclusion, the writer insisted that decided irregularities implied something serious and required a diagnosis, when that is made the appropriate treatment could easily be applied.

The Menopause, Natural and Artificial.—Dr. Arthur W. Johnstone, of Cincinnati, read this paper. He attached a good deal of importance to Stevenson's wave, as explaining many of the normal and abnormal peculiarities in the history of the menstrual function. Dr. Johnstone expressed the belief, based on observation, that the ovaries had nothing to do with menstruation; that menstruation was dependent upon a small nerve which, in order to check the flow, he tied on the under-surface of the broad ligament just before its entrance into the uterus.

Evening Session.

The Practical Workings of the Law for the State Care of the Insane.—Dr. Carlos F. McDonald read the paper. He reviewed the difficulties which had been experienced in overcoming opposition to the introduc-

tion of the new law and then of enforcing it, especially in removing patients from county institutions and poor houses into the State Asylums. The advantages which had come from the new law had been essentially those which it had been expected to bring about. Expenses had been less than under the old method, while the conditions of the patients had been improved; better opportunity had been afforded for scientific study and treatment, careful records were being kept, physicians were being given opportunity to study insanity; laboratory researches were to be made, especially with regard to brain pathology; there was to be a training-school for medical officers, these were appointed after a competitive examination; women attendants for female patients; many abuses had been corrected. The death-rate had been reduced from 11.73 per cent. in 1883 to 6.35 per cent. in 1893.

Dr. McDonald had reached that portion of his paper in which he was justifying the action of the commissioners in relation to the Poughkeepsie Asylum when his time expired.

Urethral Carunculæ.—Dr. Edward N. Liell, of New York, read the paper. The term includes vascular growths or excrescences of a soft spongy texture, arising from the mucous membrane, consisting of hypertrophied papillæ, extremely vascular, and containing nerve filaments of slow growth and exquisitely sensitive. When small they are generally sessile. From one to three, or even a dozen may be present, situated either along the borders of, or within, the meatus, or within the canal. They occur mostly in married and middle-aged women, and are accompanied almost inevitably by affections of the genital organs.

The symptoms mainly are the characteristic agonizing or excruciating pain, occurring toward the closing act of micturition; frequent micturition accompanied by more or less tenesmus; an aching or pressure about the lower pelvis and vulva, increased upon motion or contact. Patient is nervous, irritable, and depressed, added to which is a general weakness due to insomnia. Small and sessile growths the most sensitive and give rise to greater pain and distress. Urethral canal should always be dilated to arrive at a correct diagnosis and the situation of these growths, and the necessity for treatment being directed to the true indications presented.

The methods of treatment advocated are those of torsion—twisting them off, and excision—dissecting them out completely. Even after apparent removal many seem to defy our efforts, temporarily, toward a successful treatment; cocaine anæsthesia resorted to; occasionally general anæsthesia. Hemorrhage generally inconsiderable. Applications of ʒ j. to ℥ j. solution argent. nitras, gradually reduced to gr. x. to ℥ j., made immediately after operation, and each alternate day, with gentle dilatation, for a considerable length of time. In one case was obliged to perform an artificial vesico-vaginal fistula, which was closed by operation two years later, in order to give complete rest to the urethra during the interval.

The Physical Causes of Sexual Debility in the Male as Distinguished from Pyschical Causes.—Dr. F. R. Sturgis read the paper. Psychical causes were still usually regarded as the basis of sexual debility. Dr. Sturgis thought this an error, that a local cause could usually be found.

The chief symptoms driving the patient to the physician were imperfect erection, sometimes entire absence, premature emission followed by subsidence of the organ. There might be entire absence of emission, or slight amount, or imperfectly endowed with spermatozoa. Since the perfection of the endoscope we had a valuable means of diagnosis of local causes and of their treatment. Some said masturbation was a frequent cause of stricture. Dr. Sturgis doubted this, but thought it caused spasmodic stricture, which, however, could be overcome. The most common local causes were urethral hyperæsthesia, prostatic hyperesthesia, stricture, varicocele, neuralgic testicle, tubercle, syphilis, gonorrhœa. Stricture was apt to be found at two and a half, and five or six inches from the meatus. At the lower point one was apt to find granular material. A valuable internal urethral remedial agent was a solution of nitrate of silver, even as strong as from thirty to forty per cent. It was to be applied with the aid of the urethroscope.

Artificial Immunity.—Dr. H. R. Hopkins, of Buffalo, read the paper. After a general review of the subject and of its importance, he said experiments bearing on bacteriological intoxication seemed to have established the following facts: That there resided in the blood-serum a chemical substance, called by some anti-toxin, which substance possessed the power of rendering inert and harmless the ptomaïnes and tox-albumins, the disease-producing agents in all cases of bacteriological intoxication. The immense value of a method of rendering inert such poisons might be illustrated by reference to the extensive mortality caused by tuberculosis.

The Fable of the Egg.—Dr. W. S. Ely, of Rochester, in a paper with this title, described the astonishing number of eggs which patients could take with a variety of diseases, and with benefit. The number of eggs taken in some of his cases was 15, 25, and even 35 in the twenty-four hours, continued through an acute disease, or months and more than a year in chronic cases, especially those with nervous exhaustion, mental disturbance, neurasthenic conditions. One patient took 3,000 eggs in one year, another 5,475, or 15 eggs every day. Will-force was required to induce the patients to persist in the treatment.

The egg was best taken at regular intervals, say, every hour; best dropped into a tumbler and swallowed down without breaking, or other form, if preferred. Some remarkable results had been obtained, but the method was not regarded as a cure-all. Other food was not excluded, especially milk. The method had been applied also in typhoid fever, pneumonia, etc.

Spinal Supports and Braces, the Indications for Their Use, History, and Modern Perfection.—Dr. A. M. Phelps, of New York, demonstrated this subject with forty lantern slides. He showed that all of our modern methods of treating Pott's disease and lateral curvature had been understood and applied two hundred years ago. All that could be claimed for the present epoch was perfection of apparatus and methods. Dr. Phelps showed some light jackets, especially one made of aluminum, with perforations, which was very light.

Histology and Pathology of the Spinal Cord.—Dr. W. C. Krauss, of Buffalo, demonstrated this subject with lantern slides.

Diagnostic Features of Cutaneous Syphilis.—Dr. G. H. Fox demonstrated this subject with lantern slides of cases.

Lunatics in Public Places.—Dr. Wallace J. Herriman, of Rochester, in this paper referred to instances of fatal results from allowing paranoiacs or cranks to go at large.

So called harmless cranks and those entertaining any delusion, ought not to be at large; they ought to be under supervision. Would it not be well to have a paid county official, an examiner in lunacy, to whom physicians could report such cases, and who should make examination and send the patient to an institution?

Second Day, Wednesday—February 7th—Morning Session.

Secretary's Minutes Disputed.—Dr. Beach called attention to the fact that in the minutes of the previous day's session by the Secretary the motion offered by him concerning the management of institutions for the insane was only accepted and referred to the Committee on Legislation. He had understood that the motion had been adopted, and that the Committee on Legislation had been requested to act before the Legislature accordingly.

The PRESIDENT thought the Secretary's report was correct.

DR. PILCHER called for the notes of the official stenographer. These were read and stated that Dr. Beach's motion had been not only received, but adopted.

DR. SAMUEL WARD did not believe the motion had been adopted, nor that the Society would in this way reflect upon the President of the Lunacy Commission who was an honorable member of the Society.

DR. PILCHER said he felt no personal interest in this matter, but believed the stenographer's notes were correct, and moved that the Secretary be requested to correct his notes to correspond therewith.

DR. A. JACOBI moved as an amendment, that the stenographer be directed to correct his notes to correspond with the Secretary's.

The amendment was adopted, 40 voting in the affirmative, 25 in the negative.

Report of State Board of Medical Examiners.—This report was read by Dr. Morris J. Lewi. The number applying for examination had been 326, of whom only 296 elected to appear before the board, the remainder not having shown proper credentials. The board had conducted its work very economically, yet there was a bill before the Legislature to cut down the fees demanded of applicants from $25 to $5, the object evidently being to interfere with the usefulness of the board. It was hoped the Society would take action through its Committee on Legislation to prevent the passage of the bill. The report was adopted.

Dr. Porter's report as Treasurer showed a balance of $1,258.

Report of Committee on Legislation.—DR. ROOSA, chairman of the committee, read the report. It referred to work done in preventing legislation intended to render nugatory the bill which had brought into existence the Medical Examiners' Board, condemned the bill before the house reducing fees for examination to five dollars, approved the resolution adopted by the Medical Society of the County of New York asking legislation calling for examination of widwives.

The report with its recommendations was adopted.

Report of the Committee on Hygiene.—This was read by Dr. Bruce, of New York. It referred at some length to the beneficial workings of the law providing for State care of the insane and supervision by the commission in lunacy, and to the reports and action of the Health Board of New York with relation to tuberculosis as a contagious disease, and recommended more hospitals or stations in New York for such contagious diseases as diphtheria, scarlet fever, and measles. The common use among school children of the same books and pencils should be stopped, as thereby infectious diseases were spread.

Medical Examining Board, Members Recommended.—DR. ROOSA, chairman of the special committee appointed by the President, said the committee had reported for members of the State Board of Medical Examiners the following, from which the Board of Regents would select three: Drs. W. W. Potter, W. S. Ely, M. J. Lewi (present members); J. West Roosevelt, Eugene Van Sheik, of Albany, and George C. Seymour. On motion of Dr. Pilcher the report was approved.

Amendment to the By-laws.—DR. H. D. WEY read the report of the Committee on By-laws with regard to the amendment offered Tuesday by Dr. Ward. It read: Candidates for State Board of Medical Examiners shall be selected by a committee of five, to be appointed by the President. The committee recommended its adoption.

DR. LOUIS S. PILCHER moved, as a substitute, that the matter of nomination of candidates for the State Board of Medical Examiners be referred to the Nominating Committee of the Society, to be reported by them with other names at the usual time.

DRS. ROOSA, VANDERVEER, SHERMAN, A. JACOBI, and S. B. WARD spoke against the substitute, believing that the Nominating Committee would not have time to give the matter due consideration, and that there would be more direct responsibility if the President appointed a special nominating committee.

DR. PILCHER spoke for the substitute, believing that the wishes of the Society could best be expressed through the Nominating Committee.

The substitute was lost, the original motion was adopted.

President's Anniversary Address.—DR. HERMAN BENDELL read his address to a mixed audience in the Senate Chamber, Wednesday evening, taking for his subject, "The Physician of Sacred History." To speak of the Bible before the medical profession, which of all professions contained the most doubters, from whose midst had sprung innumerable philosophers whose iconoclastic views had branded the Bible as erroneous and even ridiculous—to speak to such a body would seem at the outset a thankless work. He hoped, however, to throw a little light on a neglected subject.

There was scarcely a great thought which had not been touched upon in some portion of the Bible, whether it related to law, medicine, or any other department of knowledge, life, or action. While various passages showed that there were plenty of physicians in Bible times, yet it seemed strange that no one name shone forth as the great healer, and that the Samaritan alone, a collective term, posed as the doctor of Holy Writ. That there were doctors in those days is evident; men were human and committed the same indiscretions as to-day, and suffered the same consequences.

The priests, having little to do, became doctors. They claimed to be expert in leprosy. If they had any knowledge of anatomy they must have gained it clandestinely. The word pestilence was used frequently, but meant several things. The glandular plague was very common, and it seems strange, therefore, that the Mosaic law did not suggest some manner to prevent its spread. It seemed scientific research was directed to lesser channels, and that the people were too much fatalistic to attempt interference with the plague or pestilence. There was a mysterious belief in forty days. A surgeon of the household was as much a necessity in those days as a mortgage on a Western farm is to-day. The Mosaic law encouraged the practice of medicine as shown by the command that he who wounded his fellow man should have him cured, which was in direct opposition to the custom of the heathen. The quack also existed in those days.

Elisha was a great physician, but mixed with his art some prophetic warnings, which, if made correctly to-day, would give the doctor great fame. His skill tended to make medicine popular, but later the art declined, and by the time of the Babylonian captivity, had, like poetry and learning generally, practically ceased to be. A new advent was then again ushered in with Ezra. Mohammed was mentioned as an epileptic, and while looked upon as a prophet, he recognized his own infirmity and became a student of the human body. The Mohammetans gave especial attention to the alimentary canal. They forbade wine, while the Jews drank it freely, as people did to-day, to make joy and to drown sorrow. The last part of the address made mention of the great teacher Buddha.

A vote of thanks was tendered Dr. Bendell for his chaste and interesting address.

(To be continued.)

Aluminum for Surgical Instruments.—A physician who got rid of some of his steel instruments and bought others made of aluminum says that he is sorry that he changed. The aluminum probes, sounds, tongue-depressors, and that sort of thing do not oxidize, to be sure, but he finds that they are deficient in elasticity and stay bent after pressure. He declares, moreover, that he likes to feel as if he had a hold on something when he uses an instrument, and aluminum is so light that it makes him feel as if he could put no trust in it.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DR. THORNE THORNE ON DIPHTHERIA.

LONDON, January 14, 1894.

AN interesting and important lecture was delivered on January 10th, at the Sanitary Institute, on "The Etiology, Spread, and Prevention of Diphtheria," by Dr. Thorne Thorne, C.B., F.R.S., the learned medical officer of the Local Government Board of England. The lecturer illustrated the incidence of the disease by a map carefully shaded. The dark portion of the map lies in the main down the eastern coast of England, and the next large patch of black covers the principality of Wales; the great midland centres being to a great extent free from the disease. This, said the lecturer, favors the view that the occurrence of diphtheria is favored by cold and wet; and he continued as follows: The east coast is the most wet and the coldest part of the country. Wales, on the other hand, comprises both high lands and low-lying valleys. The higher parts are cold, but in Wales it is probably more damp than cold that encourages diphtheria. The absence of diphtheria down the centre of England is the more remarkable, seeing that the area comprises the valleys of several of our largest rivers, where there is necessarily much moisture; running water is a very different thing, so far as disease production is concerned, to permanent and stagnant wetness of the soil. We have several allusions in the Bible to "living waters," meaning, of course, "running waters." These have health giving properties which the other does not possess. Diphtheria has considerably increased among us since it was first recognized in the forties, when it was first imported among us from France under the name of "Boulogne sore-throat." It was at first an essentially rural disease. It spread mostly in the hamlets and the sparsely populated districts. By and by there came a change in the incidence of the disease. At the present moment it is raging in our large urban communities. There is still an excess in the rural districts, taking the population as a whole, but cities which were formerly almost free from the disease now suffer in a steadily increasing degree, and diphtheria bids fair to become one of the diseases of urban centres. Recently we have had a very exceptional amount in London. The Registrar-General's returns for a series of weeks show that the deaths from diphtheria have ranged from 80 to 90 per 100,000, amounting during one week to 103. Such a thing has never happened before since the disease made its appearance in the metropolis. It has now abated to some extent, for diphtheria has its seasons. The diphtheria season commences about the middle of September, and goes on to the end of November. It decreases during December, and continues to do so until March or April, when there is another elevation, though much less in amount, the so-called spring incidence, and in summer there is less than at any other time of the year.

Age affects the death-rate from diphtheria in a very remarkable manner. Taking the proportion of deaths per 100,000, under ten years of age, they vary from 15 to 70. The moment you pass fifteen years of age, up to twenty or twenty-five, the deaths drop suddenly, and after twenty-five years of age diphtheria ceases to be very fatal in this country. Moreover, the deaths from diphtheria over that age occur principally among those who are brought in close contact with those suffering from it, such as nurses and medical men. The greatest age incidence, then, is between three and ten years of age.

Sex appears to have some slight influence in determining liability to it, though this is not well marked. More females die from it than males, but this may arise from their being more exposed to it than males. Little girls when they are sick are not nursed by boys, but little boys who are ill are often nursed by girls, and the same holds good in adult life.

As to the effect of unfavorable sanitary surroundings, some observers think with me that their influence has been greatly exaggerated; others hold that too much importance cannot be attached to insanitary conditions in its causation. One eminent medical man said "he had never gone over a house in which a case of diphtheria had occurred without finding some defect in the sanitary management;" but I doubt if I could visit any house except my own that did not present defects of that sort. I have not taken up a position antagonistic to the view that the sanitary condition of a dwelling may influence the disease, but I do maintain that this influence is overwhelmed by other and more important conditions.

To make this clearer, let us consider some facts in relation to the mortality from typhoid fever, in the country, in London, and, for a shorter period, in some of our large towns. Typhoid fever is essentially a disease associated with bad sanitary circumstances, and it responds more than any disease to improvements in sanitary arrangements. The saving of life in this country, owing to this diminution in the enteric fever death rate, has gone hand in hand with the improvements in sanitary legislation. There has been a great drop from 37 per 100,000 in the seventies, to 19 in 1893. This period of twenty years has been characterized by enormous progress in sanitary administration. If, therefore, diphtheria be due to faulty sanitation, we ought to be wiping it out, whereas, on the contrary, it has gone up by leaps and bounds. In 1872 the mortality was 9 per 100,000, while in 1890 it was 18, that is to say, just double. In London it began by killing 9 in 100,000, then 12, 14, 17, 22, 23, and finally 39 and 33, and it has been even higher than this during the last two years; in fact, it has nearly trebled, and this during the very period that sanitary circumstances have been undergoing every kind of improvement. I was asked before a Royal Commission, not long since, what I thought as to the influence of water in spreading the disease, and was told that a certain eminent physician had been to a house where diphtheria had broken out; he had found something wrong in the well, and he had pointed to the defect in the well and the disease as cause and effect. I am confident that there is no direct relationship between polluted water and diphtheria. As a matter of fact, the diphtheritic organism finds it very difficult to live in water. It can indeed only live in very polluted water, and average water is to a large extent destructive of its vitality.

Putting water infection on one side, much more interest attaches to the possible influence of imperfect drains and sewers. The period over which our statistics extend is the period during which our sewerage system has been amended and improved to an extraordinary extent. Millions have been spent in bringing them up to date, yet diphtheria has not lessened; on the contrary, it has gone on increasing. Again, it has been especially in our large towns that these improvements in sewerage have taken place. Early in the seventies, however, before they were commenced, there was not much diphtheria in our towns. It is since these improvements have taken place that diphtheria has made its appearance in our cities on a large scale. It is evident, therefore, that there can be no direct connection between bad sewerage and diphtheria.

Now, diphtheria is essentially an infectious disease. The emanations from the throat and mouth are intensely infectious. By expectoration and otherwise the poison gets into the sewers and cesspools, and in that way I dare say they may become contaminated by diphtheria, and so the disease may be caused by emanations from a diphtheria-infected drain. Just in the same way as the sewers, the soil itself may be contaminated. I am convinced that there is some relationship between the influence of soil and diphtheria, and this influence appears to vary with movements in the level of the subsoil water. In river valleys especially, there are constant oscillations of

the subsoil water. When the water-level rises the diphtheritic and other organisms in contaminated soil are washed up and their emanations are expelled, and so diphtheria may be possibly caused. The possibility of such a sequence of events may therefore be conceded. We hear sometimes of what is called "drain-throat." I do not know exactly what this may be, but it seems certain that people who inhale effluvia from drains (and the better the house, the more pipes are there to convey the noxious vapors into the interior) do get a form of sore throat, just as medical students and nurses in hospitals get what is called "hospital sore-throat." There are thus two ways in which the sore-throat caused by sewer emanations may lead to diphtheria. I have a strong impression that diphtheria never attacks a healthy throat. I will not undertake to say what constitutes a healthy throat, but from the moment you get an inflamed and denuded sore-throat there is nothing the diphtheritic organism likes so much as to fasten upon it. Drain emanations, therefore, do not cause diphtheria, but they prepare the soil for the development of the specific organism of the disease.

I am credited with having a diphtheria theory of my own. One can never be sure of the amount of originality that can be fairly claimed in such a matter; but in making some investigations in certain parts of the country I have had my attention called to circumstances also observed by others. Take, for example, the Welsh valleys. There we find the houses built on the slope of a hill, built right into the hill, so that the walls are always wet and the floor is always mud. During the cold weather the people all get sore throats, and if you look into their throats you will almost always find traces of ulceration due to past attacks of inflammation of the tonsils. The sore-throat—an ordinary sore-throat, so far—is passed from one to the other (for all forms of sore throat are apparently infectious), and by and by—as I have observed over and over again—it gets worse and worse, until it culminates in an outbreak of diphtheria. The explanation that occurred to me, in respect of these circumstances, is a progressive increase in the infectiousness of the organism which produces diphtheria. There is nothing irrational in such a view, although certain distinguished bacteriologists did not take kindly to the idea. They hold that just as cats, cows, and dogs always produce cats, cows, and dogs, so the various microorganisms must also breed true. To some extent, and in respect of certain organisms, this may be so. If you go to a house where there is measles you do not expect to catch whooping-cough; or scarlet fever where a patient is suffering from typhoid; but it seems to me that some diseases are probably more stable than others, and I think diphtheria is among the unstable, and that it is capable of acquiring disease-producing properties which it did not previously possess. This is the property of progressive infectiousness to which I have alluded. We know that if you take a wild plant from the heath where it has been kept alive with great difficulty, and place it in a hot-house under specially favorable circumstances of temperature, soil, etc., it will in a few generations develop properties vastly different from those it originally possessed while growing on the heath; and if relegated to the heath once more, after a time it gradually loses these properties and returns to its original conditions. If we apply this train of reasoning to the organism of diphtheria it will be seen how, under favorable conditions of environment and soil, it may develop properties which it did not possess in the first instance.

A thing more difficult to deal with is the manure nuisance. Certain it is, by coincidence or otherwise, that outbreaks of diphtheria have occurred at places along the Thames where London manure is deposited, and it is quite possible that the manure may have been the vehicle of transmission of the poison, especially since it has become so general in our midst.

A definite relationship has been alleged to exist between scarlet fever and diphtheria. Now, I have never seen or heard of a case in which scarlet fever followed diphtheria, while there are hundreds of instances in which the patient convalescing from scarlet fever has contracted diphtheria. This, I maintain, is only another example of the tendency of the diphtheria organism to attack sore-throats generally. The scarlatinal sore-throat affords the organism the gate of entry, where it can fix itself and develop under favorable circumstances.

Diphtheria is a disease specially prone to attack children between the ages of three and ten, or five and twelve, but it is very difficult to determine for certain how far it is simply a question of age. It is at the age of five or six that children begin to go to school, and five to fifteen may be regarded as the "school incidence," though plenty of children go to infant schools even before that age. In a village in Essex in which upward of 1,400 persons were attacked, I found there were 272 cases under three years of age, but between three and twelve, the special age incidence, the number was 928, and between twelve and fifteen, covering the remainder of the period, the number was 210. This shows the special incidence affecting children between the age of three and twelve But, of course, the majority went to school at that age, so separating those who went to school from those who did not, I found that, while among those who were known to go to school the proportion was fifty-nine per cent., the proportion being 0 and 3 (before the school age) was only one per cent., and only five per cent. among those aged between three and twelve, who for any reason did not go to school. Mr. Power, whom I consider to be the greatest etiologist of the day, has succeeded in showing that not only is the incidence greater among those who go to school, but that by the mere aggregation of children in school it is easy to manufacture a marked degree of malignancy. He investigated an outbreak in a district in which it was possible to know every child, and to follow their movements. The schools were in working order, and taking the age incidence between three and twelve, he found that 16.6 per cent. of those attending school had contracted diphtheria, as compared with 3.8 per cent. among those who did not go to school. Children who contract diphtheria at school may easily carry the infection to others who remain at home, so that this proportion of 3.8 per cent. is possibly susceptible of a reduction. The schools were closed for many weeks, and when reopened 4.8 per cent. of the scholars contracted diphtheria, whereas none of those who stayed at home caught the disease. Again, the schools were closed and greater precautions were ordered. When reopened this time, the proportion attained 7.1 per cent. among those who went to school, while only 2.5 per cent. of those who did not go were attacked. After closing again, on the fourth reopening 4.1 per cent. of the children contracted the disease. Between these periods there was not a single case of sore-throat known to exist anywhere. This seems very remarkable, and the events show clearly the influence which school life exercises on the spread of the disease.

School brings together the most susceptible members of the community, under circumstances which are peculiarly favorable to infection. The children are close to each other, and in saying or singing their lessons they have every facility for breathing into the faces and mouths of their near neighbors. Consequently a child with a trace of diphtheria can easily infect the others. The Education Department requires so much wall-space and floor-space, but the available floor space is largely monopolized by the teachers, while the children are piled up at one end, so that the object of giving so much floor-space is frustrated. The greater the want of ventilation, the greater the risk. Then, too, children of young age are very fond of passing on sweets from mouth to mouth, and of drinking out of the same unwashed cup, thereby offering greater opportunity for serial infection.

I am afraid the school attendance officers are largely responsible for spreading the disease. They stimulate attendance without inquiring whether or not the child

had been kept at home on account of sore-throat. And in the rural districts, the parsons have worried every child into attending school. It was years before the increase was seen in London, but some change has evidently come to pass in our great cities; and this change, in my opinion, is compulsory education, acting by causing the aggregation of the most susceptible members of the community, under conditions favorable to the spread of diphtheria. Of course we cannot stop elementary education, but it may be possible to modify the circumstances which I have shown to be potent factors in spreading the disease.

The next question is the possibility of infection by milk. A large number of outbreaks have been distinctly traced to milk, and many of the most obscure outbreaks in former years would have been easily explained had this method of infection then been recognized. The milk may be infected by a person suffering from the disease, for if the germ falls upon the milk, this affords it an excellent medium for growth and development; but I do not think that this is often the case. A far more frequent cause in my opinion is the existence of a disease in the cow itself. In inquiries into certain outbreaks it has been shown that the disease followed particular "milk walks," that is to say, the *clientèle* of particular dairymen. It has even been traced to particular sheds, and finally to particular cows. Of course you must allow for secondary infections, so your inquiries must bear on the first cases only. Of course a considerable number of the persons who drink the milk escape, but this cannot excite any surprise. It is a common experience. It was, however, noticed that children who were habitual milk consumers suffered the most, whereas those who took little milk, and that little either boiled or only in tea, etc., escaped. Again, those who took cream suffered more than those who did not, an observation I had already made in respect of typhoid infection. I took this merely to be the mechanical effect of the oil-globules in rising, taking with them the germs to the surface. With regard to diphtheria, however, Mr. Power has shown that this is not the case. He finds that those who take fresh milk suffer less than those who take skimmed milk or cream, and the point with him is the keeping the milk too long. If you partake of an infected milk while it is yet fresh, you only take a certain, probably a small, dose of the poison, because the germs have not had time to multiply to any great extent. If, on the other hand, you take milk that has been standing twenty-four hours, the germs have had plenty of time to develop and multiply, and the dose of poison is proportionately greater. The lesson to be learned is to leave off drinking raw milk altogether, and you will escape many diseases—diphtheria among the number. I believe we are almost the only nation addicted to drinking raw milk. Some tribes in India would no more think of drinking raw milk than of eating raw flesh; but whether they rejoice in any immunity from diphtheria from this cause, I cannot say.

Many of the lower animals have been suspected of constituting a danger in regard to diphtheria—cats, for example. The question may, of course, be asked whether it is the cat that gives the diphtheria to the child, or the child to the cat. One thing is certain; viz., that the cat can be inoculated with human diphtheria, and suffers from definite, well-marked, and specific symptoms typical of this particular disease, and that the diphtheria organism can be found in its dejections. Although I have little doubt as to the possibility of a diphtheritic cat passing on the malady to the child, I do not think much diphtheria is contracted in that way. But there is the cow! When these outbreaks were traced back to particular sheds, there was always the possibility of finding cows suffering from some disease. Now our knowledge of the cow is vague; but one frequently finds that the cows have been suffering from a disease associated with a rise of temperature and the formation of vesicles and pustules upon the udder, the animal being evidently out of health. You can often trace the disease actually to the particular cow, and the cow was always affected in this way. An objection that is frequently urged in such cases is that there was someone on the farm who was suffering from diphtheria, and who might have contaminated the milk. But there is nothing extraordinary in some of the persons on the farm being affected. It would indeed be extraordinary were it otherwise, for they are naturally the first to be exposed to the infection. If you take diphtheritic matter from a sick child and inoculate a milch cow—it is essential that it should be a milch cow—Dr. Klein has found that the animal develops a disease which, he says, he is absolutely unable to distinguish from that found in the cow living in the sheds to which the milk had been traced. On the fifth day vesicles, pustules, and ulcerations make their appearance, and material from the vesicles contains the typical organism as found in the human subject. He inoculated a cat with it, and the cat developed diphtheria. Still further, some of the milk from this diseased cow was accidentally given to a cat, and the cat developed typical diphtheria. I think a large number—if not, indeed, the great majority of our specific diseases come to us through the lower animals, or have come from them in the past. I have just said that diphtheria is not a stable disease like certain others, but for this very reason I think we ought to lose no time in taking the necessary measures to diminish its incidence before it has had time to become stable.

Diphtheria is essentially an infectious disease, and the most frequent source of infection in this country is infection from one person to another. It is, therefore, necessary to isolate patients, and in most cases this can only be done by isolation in hospital. Those who have paid a visit to isolation hospitals on a large scale will admit that the system is not altogether satisfactory. The mortality, moreover, is terrible, without one being able to say why. This may be due in part to the fact that probably only the severer cases reach the hospital, but I am convinced that the principle of aggregating patients suffering from infectious diseases in hospital is altogether wrong. On the other hand, the advantages to such infectious patients of special care, nursing, feeding, and medical attendance may more than compensate for the enhanced risk.

What we require is a large amount of air space, but that means money in construction, land, management, etc. What we really want is linear space, and I care nothing for mere cubical measurement. A hospital may be as lofty as you please, but if the patients are packed closely together on the floor, the ventilation will be deficient, and the place will be unhealthy. Efficient ventilation, which means a large amount of wall space, is the only way to avoid the evils of aggregation.

Where sore-throat ends and diphtheria begins I cannot say, but no child who is suffering from any form of sore-throat should be allowed at school, nor even anyone from the house in which that child resides. In regard to the closing of schools, the education department makes some allowance when the school is closed by order of the medical officer of health, so that the grant may not be lost on the ground of diminished attendance. It may not be always desirable or necessary to close the schools altogether in some districts. There is a central village in which the church and school are situated together, with several outlying hamlets, A, B, C, and D. An outbreak of diphtheria may occur at C, no children from that hamlet ought to attend school, but it would be a mistake to close the school altogether, because then the other children would have time and opportunity to frequent C and catch the disease. While they are at school, at any rate, they are protected against this particular source of infection. Unfortunately the education department makes no provision for this contingency, and the school suffers in grant by reason of the non-attendance of the scholars from C. This is a discrepancy which ought to, and probably will, receive immediate attention at the hands of the department.

DOES EATING VEGETABLES MAKE THE BIG MAN?

To the Editor of the Medical Record.

Sir: In your issue of January 20th Mark I. Knapp contributes an interesting communication upon the physiological and pathological influence of vegetables upon man. The first part of the article shows scientific soundness and much care, and the statement that "both vegetables and meat are of like importance to sustain our equilibrium of health and life" is, I believe, for the *fin-de-siècle* individual, generally accepted.

After laying a very good scientific foundation upon food in general, the writer makes a very bold statement, calling Paolo Riccardi to the rescue, who, in substance, has said that vegetables bring forth tall men, while animal diet produces short people. The writer follows this up and settles the matter, as he believes, so conclusively that one might be led to feel that Darwin, Herbert Spencer, Huxley, and Wallace had wasted much time trying to fathom a subject so easy to understand. "It's not climate," says the writer, "no, nor hill, nor valley, nor heredity that makes the big man big and the little man little, but diet only. It is vegetables that produce height in animals and man."

In animals we are told the proof is easy, and we have but to contrast the vegetarian elephant and ox with the flesh-eating lion and fox, to be convinced at once that it is diet alone which determines the size of these quadrupeds. Our attention is further called to the fact that the herbivora are proportionately built, the height equalling the length of the body, while the carnivora are destitute of all proportion, having short legs. The writer here must have been thinking of the carnivorous greyhound, or dreaming of the fine proportions of the herbivorous rhinoceros or giraffe. When he tells us the herbivora are larger, and larger on account of food only, he may have been dwelling upon our ancient friend the ichthyosaurus, or on our more modern type of carnivorous brevity and compactness — the balæna mysticetus or whale-bone whale.

Regarding the latter, however, he may wish to limit his remarks to terrestrial carnivora. He may even wish to think with those of our zoölogists who question a place for these monsters among carnivora at all, notwithstanding the fact that our balæna mysticetus devours immense quantities of crustaceans and pteropods, and in modern times has never been known to hunt a watermelon patch or tread down a cornfield.

Having settled the point that the size of animals is due to diet alone, by contrasting the big herbivorous elephant with the little carnivorous fox, we are led a step further and told that "the ethnography of man proves with certainty and positiveness the same thing." We are invited to study primitive people who have not been civilized by the railroad and telephone. "Look," says the writer, "at the Esquimaux and Lapps of the North and the Patagonians and Polynesians of the South What a difference of diet in those extremes!" While telling us that the Esquimaux eat animal food and are small, he leads us to infer that the Patagonians are large because they are vegetarians. That the latter are large is correct —they are very large. While the older voyagers exaggerated somewhat when they used to say that when a Patagonian stood with his legs apart an ordinary man could walk between them without stooping, nevertheless they are known to compare in stature favorably with picked English life-guards.

But, alas! these same Patagonians are not vegetarians. On the contrary, they subsist almost entirely upon the guanaco, one of the llama tribe. This is the creature they spend their time in hunting. This is the creature that supplies the big Patagonian with food, clothes, and dwelling. Our writer must also have lost sight of our North American Indian, in his wanderings for short-legged and primitive animal feeders.

It is a fact that the majority of primitive men were small, notwithstanding the fact that the majority of them were vegetarians. The mass of evidence shows some connection between barbarism and inferiority of size, *e.g.*—

South American races: Guiana Indian is mostly below 5 feet 5 inches; Arawâks seldom more than 5 feet 4 inches; Guaranis rarely 5 feet.

Northern Asia: Kirghiz, average 5 feet 3 inches.

Southern Asia: Tamulian aborigines of India are described as smaller than the Hindus; Puttooas do not exceed 5 feet 2 inches; Lepchas average about 5 feet; Juángs less than 5 feet.

Many Fuegian tribes are not more than 5 feet; Andamenese men vary from 4 feet to 5 feet; common height of the Veddah is 4 feet 9 inches; the ordinary height of the Bushman is 4 feet 5 inches. This diminutive stature, too, in spite of the fact of a diet of nuts and fruit, or, like the Fuegians, subsisting mostly upon fish and mollusks.

Why then look no further than to connect the small size of the Esquimau and Laplander with the animal diet? Does not the severe climate entail physiological cost? Is it not as unreasonable to attribute the small size of the Esquimau and Lapp to their animal diet as it would be to attribute the small size of the Shetland pony to a vegetable diet?

The Bushman, on the other hand, had to face a barren and arid territory, scarcely inhabitable by any class of human beings—a lower standard of growth is the natural outcome.

Mr. Knapp also directs our attention to the short legs of the carnivora and primitive flesh-eating tribes like the Samoyedes, Obongos, Kenkobs.

We may state that this shortness of legs is by no means peculiar to flesh-eating tribes. It is an established scientific fact that small lower limbs characterize early types of humanity irrespective of diet, *e.g.*, Ostyaks, Kamschadales, Kookies among the Hill tribes of India; Chinooks and Guaranis among the American races. So, too, we find "short bandy legs in the Fuegians, Akkas," etc. Relatively short legs predominated in our Simian ancestors, and still persist in early man.

Again in primitive man we find large jaws and teeth and a large digestive apparatus. This is clearly put forth by such authors as Barrow, Schweinfurth, Tennent, Galton, Dr. Hooker. Ancient British skulls show large massive jaws. The big jaws and stomachs clearly point to the true vegetarian diet of these early people, and plainly tell us that they ate coarse food, "filling their bellies with the husks that the swine did eat;" or, like Nebuchadnezzar of old, eating the grass of the field. In spite of so many vegetables they remained short, bandy-legged individuals of primitive times.

Must we not then seek for other factors than food to explain stature, else why does the famous English black horse continue to tower in size over the "ganon" of the Scottish Highlands be they fed with the same food for many years in the midland counties of England, or graze together on the moors of the Cheviot Hills?

If food alone determines size, why such disparity between the famous short-horns of England, the Jerseys, and diminutive Shetlands—the latter scarcely exceeding in size a long-wooled wether—and this disparity in size remaining if our tiny Shetlands are imported into the lowlands, eat the same herbage, and tread the same pastures with their short-horned companions? Again, why does the progeny of these two widely separate groups approximate in bulk to their sires? If food only, why do the Pembrokes and Anglesea cattle, both mountain types, display such difference in size?

We are told that herbivora have large heads and large skeletons, yet the most marked feature of the famous Leicester sheep, who wallow in the rich vegetables of the lowlands of England, is the smallness of their heads, and of their bones generally, as contrasted with the weight of carcass.

There are valleys in Scotland lying almost side by side where the average heights of the men vary three or four

inches, the evident explanation here being a different clan origin.

The records of the British army show that the Goorkhas of India, living on grain and ghee, average five feet four inches, while the Afghans, who are allowed meat once a day, average five feet eight inches.

Does not, then, the *post hoc, propter hoc* reasoning attributing the size of the elephant to his vegetable diet, and that of the fox to his animal diet, point to lack of thought? One is reminded here of Lincoln's story when he was pitted against an adversary in a court of law. His adversary had talked much without, apparently, much logic, and Lincoln remarked that he did not know what to compare this random thoughtless talk with, unless to a steamboat upon which he was once going down the Mississippi. The steamboat was the possessor of a five-foot boiler and a seven-foot whistle, and whenever the whistle blew the boat stopped.

To conclude, food plays its part, and a very important part, in establishing stature; so does climate play its part, and heredity and altitude and environment. No amount of vegetable food would make the Esquimau large, or materially add to the size of the Jap under existing environment. Centuries must indeed pass by for marked changes in race to manifest themselves. The short-legged and big-bellied members of our early hunting tribes gradually gave way to longer-legged and more symmetrically shaped individuals. Those possessing the longest legs were better able to cope with powerful and swift creatures, and escape from their enemies, beast or man, and thus was gradually developed the higher stature of our hunting tribes of yesterday and to day.

Through the modern process of selection and training the dray horse is made to lose his gigantic digestive apparatus, his thorax narrows and deepens. The lung capacity is increased at the expense of the stomach, the limbs become more lithe, the form more graceful, and, gradually, the racer is evolved.

Natural selection and sexual selection are factors at work, which through countless ages have increased size when size became an advantage, or reduced size when natural advantages called for such change. Man has not escaped the working of these factors. The small man possessing greater prolific properties and hardihood to withstand the severity of certain climates has been as certainly adjusted to his place as the big man to his. This building up or tearing down goes on just the same whether man gains his chief sustenance from the blubber of our arctic regions, from the potato patches or cornfields scattered over the earth, from the animals about, or from the fruits of Brazil, "the country where the nuts come from."

GEORGE R. ELLIOTT, M.D.

48 EAST TWENTY-SIXTH STREET.

BLOODLESS AMPUTATION AT HIP-JOINT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Whether the "Wyeth method of hip amputation" be "properly named" or not is a matter of little interest to most of our profession. It is now so widely accepted and so well established, and the facts which justify this acceptance are so simple and easy of demonstration to any person of intelligence and fairness, that a discussion of the subject has very little personal interest to the writer.

If anyone will read my operation as described in the MEDICAL RECORD of January 13th, and then read the technique given by your correspondent in the MEDICAL RECORD for January 27, 1894, it will be evident the methods are unlike. The only real point of similarity is that the lower extremity is removed at the hip-joint in both procedures. I am indebted to your correspondent for citing me to the operation advised (but never performed) by Volkmann in 1886, which had escaped my notice, and to which my first operation bears a close resemblance. Volkmann advised the elastic constrictor to be carried from the femoro-perineal fissure, or crotch, up over the pelvis "between the upper and lower iliac fossæ."

This method of controlling hemorrhage is very like and not as efficient as that devised by Jordan Lloyd in 1883 (*The Lancet*, 1883, p. 897, Vol. I.), in which "a strip of black india-rubber bandage about two yards long is to be doubled and passed between the thighs, its centre lying between the tuber ischii of the side to be operated on, and the anus. The ends of the rubber are now to be firmly and steadily drawn in a direction upward and outward, one in front and one behind to a point above the centre of the iliac crest, etc." Mr. Lloyd advises a compress to be laid over the iliac artery on which the rubber rests, and his bandage is carried only a little higher.

In my method the rubber-tube constrictor goes around the thigh a number of times at the level of the junction of the head and neck of the femur, is held absolutely and safely in this position by two steel skewers properly inserted, occludes perfectly every vessel in the field of operation, and permits the disarticulation and deligation of all vessels before the tourniquet is removed.

In the earlier operation I advised sawing the bone through below the trochanter and then enucleating afterward, but later personal experience, and that of other operators (more particularly Professors Murdoch, of Pittsburgh, and McCosh, of New York), led to a change of technique in leaving the femur undivided to aid in disarticulation.

The method of dividing the bone and enucleating, which Volkmann advised in 1886, was done, as I have already shown, by Brashear, of Kentucky, in 1806, before Volkmann was born. The surgical acumen of your correspondent, and the animus of his criticism are evident in the line which reads, "I am willing to give to Dr. Wyeth the credit of introducing the pins, and thus needlessly mutilating the thigh." Well-informed surgeons will not apprehend any serious mutilation of the thigh from the use of a clean steel skewer, three-sixteenths of an inch in diameter, which transfixes the skin and superficial tissues on the outer and inner aspects of the hip, well away from every nerve or vessel of importance, especially when there is nothing left of the thigh but a short and shrunken stump.

I have implicit faith in the spirit of fairness which prevails in our profession, and believe that whatever credit I am entitled to for devising and developing the "Bloodless Amputation at the Hip," will be accorded me.

JOHN A. WYETH, M.D.

A RULE WHICH OUGHT TO BE RESCINDED.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Some time ago a regulation was made at the New York Academy of Medicine which forbids the use of the library after six o'clock to non members. We have heard much criticism of this regulation and no defence. Its condemnation comes from the members of the Academy themselves and not from non-members. The only argument we have heard in its favor is that free admission in the evening is liable to cause crowding in the library and so restrict the rights and privileges of those who, as members, have a prior lien thereon.

We are opposed to the rule from every point of view. We have been fairly frequent attendants at the library ourselves, both day times and evenings, and have never seen over a dozen persons there at once, and rarely that number even. It cannot be that there is such a sudden and overwhelming desire for knowledge on the part of the local profession that the supply either of alcove-space or chairs fails to meet the demand.

The Academy building is not a club-house. It is, in a sense, a public institution, deriving certain corporative privileges which in turn imply certain obligations toward the public, whether medical or lay; and one of these is that the library should be managed in such a way as to invite its freest possible use. We have not heard of any

gross abuse of its facilities, and are at a loss to know why this short-sighted policy was inaugurated.

For such a policy is short-sighted to the last degree. The grand work of the Academy needs to be supplemented by liberal donations from the public in order to enable it to fulfil its true mission; but how much enthusiasm would the average citizen feel over it, if, on attempting to visit the library in the evening (the only spare time New York men have), he is faced with this rule which forbids his entrance? Would he be apt to go home and change his will in favor of the Academy? We trow not.

If it be said that the absence of all restriction gives to non members, who pay nothing, the same rights as to members who pay twenty dollars a year, we say, that, to be consistent, non-members should be excluded altogether. We have neither sympathy nor patience with that philanthropy which closes its operations at sundown.

Furthermore, the Academy will not permit a man to become a member until he has been a graduate in medicine for three years. This rule is wise, but it seems hard to shut a man out of the library in the evenings who would be glad to become a member but is debarred by an arbitrary rule of the Academy as to age in medicine—just as the latter may be.

Moreover, to many young men, just starting their professional life, the necessary expense of Academy membership is a temporary obstacle to their joining. In time they will become members if they are treated properly. To antagonize them at the outset is neither courteous nor politic.

In fact we can find no qualification for the rule whatever, unless, perhaps, some Academy magnate on entering the library found a luckless first-year student reading his favorite copy of the *Kalamazoo Speculum* or the *Archiv. für "Crank"-heiten.*

Gentlemen of the Academy, abolish this foolish rule. It is faulty in theory and puerile in practice.

BOOK-WORM.

January 29, 1894.

FREUND'S NEW OPERATION FOR PROLAPSUS UTERI ET VAGINÆ.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The *Centralblatt für Gynækologie*, No. 47, 1893, containing an article by Dr. Hermann W. Freund, "Eine neue Prolaps-operation (Vorläufige Mittheilung)," reached me just as I was about to operate for radical cure upon four cases of total procidentia of the uterus and vagina, then under my care.

As a result of the perusal of the above article the plan of operation was changed in three of the four cases, greatly to the benefit of the patients and the satisfaction of the operator. To the fourth case the new operation was inapplicable.

Indeed the hope of being instrumental in procuring the same satisfaction for some one situated just as I was when the paper reached me, but who may not have access to it or may not be able to read the article in the original, and the expectation of correspondingly benefiting his patient or patients, prompts me to indite these lines. Through your esteemed and widely distributed journal, my hope is more than likely to be realized.

Freund's new operation consists essentially in narrowing the vagina, to any extent considered desirable, by a number of interrupted, permanent, circumvaginal, buried sutures. The first suture surrounds the vagina a little below the vaginal junction. The second is placed around the vagina a little further down, and so on until the site of the hymen is reached, where the last suture is introduced. When and while all the sutures are in place, it is impossible for the uterus to come down. Freund uses the buried silver-wire suture, and appears to think it the only one applicable. I have, however, in my three cases, used the buried silkworm-gut suture, which, for reasons of flexibility and readier adaptation to the necessary movements of the parts, I consider superior to silver wire.

The operation is simplicity itself, requiring no denudation nor resection of parts. It is practically bloodless, the only bleeding possible being from the needle punctures. Anæsthesia is unnecessary, though, from my own experience, I would recommend it at least in the first few trials. The patient leaves her bed on the following day and goes about her business, if an anæsthetic be employed. When narcosis is dispensed with, she need not take to bed at all. No preparation is necessary for the operation, except where vagina or cervix are the site of erosion ulcerations. A preliminary treatment of a week, or thereabouts, will suffice to cure these, and the operation can then be performed.

With a normal uterus and appendages, and the absence of a tumor or collection of fluid in the abdomen, the only contra-indications to the operation lie in the necessity or desirability of a continuance of the sexual relations, and the possibility of a future pregnancy. Even with these limitations of indication, the operation appears to me applicable to the majority of cases of total prolapsus of the uterus and vagina as we meet them.

For the technique, as well as a graphic delineation of the operation, which makes it intelligible at a glance, I must refer the reader to the original article of Freund.

My own cases were operated upon on January 12th, 13th and 17th of this year. The ages of the patients were respectively sixty, sixty-one, and fifty-one. Five buried sutures of silkworm-gut were applied in each case. The result thus far has been perfectly satisfactory to my patients and to myself.

In conclusion I wish to predict for the new prolapsus operation, as soon as it becomes more widely known, the grateful appreciation of a vast number of physicians and women the world over. By reason of it the name of Hermann W. Freund will prove as enduring as gynecology itself.

GEORGE M. EDEBOHLS, M.D.

NEW YORK, January 28, 1894.

STERILIZATION IN CRIMINOLOGY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The article of Dr. James Weir, Jr., in the RECORD of January 13th, on Criminal Anthropology, furnishes a strong argument against a strictly punitive treatment of confirmed, habitual, or congenital criminals, but we must not forget that, however strong a natural impulse may be, there is always a possible restraining force in a salutary fear of punishment; even the insane may be, and are, benefited by discipline. Clearly society has a right to protect itself against the criminal classes, and may avail itself of any means, not in itself cruel, which will restrain violence or crime in any form. The penalties of the law should not be looked upon as primarily punitive, but rather as restraints, and clearly any measures may, and should be, taken which may best attain this end, namely, to protect the public. Dr. W. S. Cheesman, in the RECORD of January 27th, commenting upon Dr. Weir's paper, offers castration and spaying as a means of attaining this end. Probably Dr. Cheesman has not read a book entitled "Criminals and Paupers," by Henry M. Boies, whose official position in Pennsylvania has made him familiar with the criminal and pauper classes, and who warmly advocates the same method of mitigating the disproportionate increase of the criminal classes. He points out that, while in the last decade, our population has only increased 24.5 per cent., the classes above referred to have increased 45.2 per cent., a condition certainly calling for some energetic means both of prevention and correction.

In Chapter XV. of the above-named work, the author, under the heading "Degeneration and Regeneration," elaborately and forcefully proposes sterilization of habitual criminals, as offering the most effectual and humane barrier to increase of crime. Certainly the time has

come when we must recognize the necessity of advancing on new lines, if we hope for success.

Steadily, day by day, the ever-increasing procession moves to our prisons and almshouses. It is made up largely of men and women who, after a brief stay, are let out to prey upon the community and again join the motley throng.

It is not probable that the public sentiment can be educated up to the sterilization point for many years to come; for however humane the measure may be, it will seem to most men to be cruel. A law which shall declare a man or woman who shall have committed and been convicted of crime a given number of times, an habitual criminal, and shall direct that all habitual criminals must be detained for life—quarantined one might say—where they may no longer ply their criminal pursuits, and when, with healthful food and surroundings, and humane treatment, they shall be obliged to lead industrious lives, will strike most people, I think, as equally effectual and more humane than sterilization. The conviction, however, of an habitual criminal, must be mandatory, upon evidence furnished, and there must be no pardoning power vested in a governor or other official, but a ticket of leave might be issued by a properly constituted committee upon evidence of good behavior, at the expiration of ten years of the life sentence. Necessary as some such measure as this seems, and desirable as some moral quarantine has become, it can only be attained, it is to be feared, after long agitation and effort. It seems only fair and proper that physicians, who look upon such questions from their natural and physical sides, rather than from a sentimental view, should lend their teaching and aid to the movement for a radical treatment of this condition.

S. S. Jones, M.D.

20 East Sixty-third Street.

Work as a Therapeutic Agent.—A correspondent has sent to the *Spectator* the following short letter from Sir Andrew Clark: "Dear ——: There are two things about all patients which help us to discover their maladies: what is found by the physician and what is felt by the patient. What is felt helps us very little; what is found, for the most part settles our judgment. What is felt by Mr. —— amounts to a great deal. Various disturbances of digestion, weakness, inaptitude for work, recurring faintnesses, malaise, and the feeling of getting worse and worse. What I found amounts to very little. . . . Every organ that I can reach is free from obvious structural disease; and as the patient has suffered for years in this way and nothing has come of it, it is reasonable to say that there is no structural disease. Mr. ——, therefore, is ailing, and perhaps suffering, but not, in the ordinary sense, ill; furthermore, I think that he is introspective, morbidly nervous, and occupied with himself. He cannot at present be made well; but he may reach his best by a simple regular diet, by self-effacement (dying to live), by light, regular, daily occupation, by the resolution to give a deaf ear to his trying sensations, and by a determined fighting and struggling to lose himself in outward things. . . . To do nothing would be to go backward and downward. True, he may suffer if he works; nevertheless, it is best to work. Hundreds suffer to work. I have always suffered to work, but work keeps me where I am; I have to wrestle with it, but thus my antagonist becomes my best helper. Yours sincerely, Andrew Clark."

Inordinate Zeal.—Dr. A. C. Follett, of Schenevus, N. Y., writes: "A man recently called upon me for treatment for chonic constipation. I told him he could probably cure himself without medication if he would establish the habit of going out regularly, at about the same hour each day, and making vigorous expulsive efforts to move the bowels. He said he had practised this already until he had produced double inguinal hernia, and believing '*Alia tentanda via est*,' he got some drugs and a truss."

New Instruments.

THE ANNULAR SEPTUM KNIFE

By WALTER F. CHAPPELL, M.D., M.R.C.S. Eng.,

New York.

Surgeon to the Manhattan Eye and Ear Hospital, Throat Department.

The annular septum knife, as shown in the cut, is made in two sizes, and consists of a handle, an angular shaft, and a slightly curved ring-knife. The following measurements are for the larger size: handle, three and one half inches long; shaft, two and three-fourths inches; ring one-half an inch in length and three-eighths of an inch in width. The ring is oblong and curved a scant eighth of an inch from the plane of the shaft. The anterior two-thirds of the inside of the ring is bevelled and terminates in a sharp edge which flares out sufficient to engage the tissues. To use the knife the ring is pressed against the tissues and drawn with moderate force toward the operator. The smaller ecchondromata shell out of the mucous membrane like a pea out of its pod, leaving the mucous membrane attached anteriorly, so that it can be replaced or cut off. A large ecchondroma may require several parings, which would remove it in successive layers.

This instrument may be employed for the removal of all anterior ecchondromata; localized thickenings of the septum; after saw operations, to remove the tissue which remains at the lower edge of the saw cut; also after drill operations, and for papillomata or granulation tissue growing from the septum. Growths on the posterior border of the septum and posterior hypertrophy of the inferior turbinated bodies, can also be reached in this way. The angular shaft allows a good view of the field of operation; cutting toward the operator and the smooth surface left are great advantages. With children this instrument is of special value, as it takes away the idea of a knife and can be used rapidly. The edge should be kept sharp.

22 East Forty-second Street.

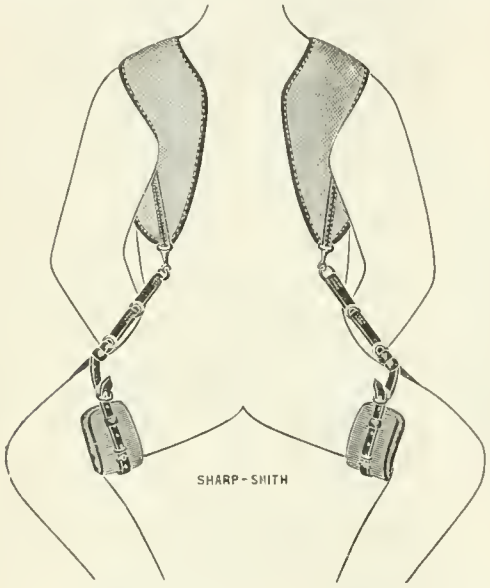
AN INSTRUMENT FOR REMOVING FOREIGN BODIES FROM THE IRIS AND ANTERIOR CHAMBER OF THE EYE

By EDWARD SWASEY, M.D.,

Worcester, Mass.

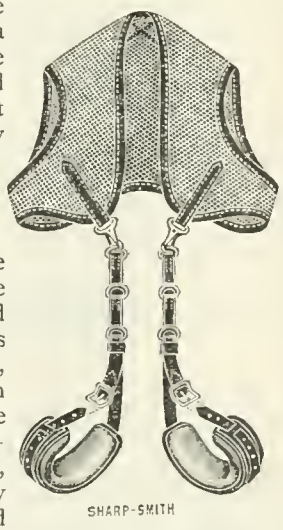
Oculist and Orist to Worcester City Hospital.

The instrument here illustrated is designed to enter the anterior chamber and grasp any foreign body that may be resting on the iris or attached to it, and preserve the aqueous fluid until the instrument is partially removed. It acts on the principle of two Graefe knives back to back, and the cutting edges turned outward. As the blades increase in thickness and breadth from point to base, their form is wedge-shape, and no fluid will escape until withdrawal is commenced, or until at least the body has been grasped. It looks like an easy matter to remove a small particle of granite or steel which we see attached to the front of the iris, while yet the anterior chamber is perfect. But once let the aqueous escape, and the iris come forward against the posterior surface of the cornea, and it is then next to impossible to remove this



small foreign body without also drawing out a portion of the iris, and doing an iridectomy. But if we can once grasp the body before the fluid has escaped we simplify the operation. This instrument will accomplish this object. In case of steel particles we could make a magnet of the blades, and so give additional retentive power. It certainly retains the aqueous, as I have proven by a number of experiments. The cut illustrates nearly the actual size of instrument. E. B. Meyrowitz, of New York, made the instrument for me.

JACKET SUPPORT FOR LEGS IN PERINEAL OPERATIONS.[1]



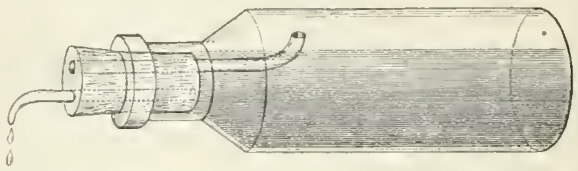
By H. W. BASSETT, M.D.,
OAK PARK, ILL.

Through the medium of this journal I would like to introduce to the profession a little device for supporting the lower extremities in perineal, rectal, and obstetrical operations. It consists of a canvas jacket cut very short

behind, and with large armholes. The front is cut square, and at the lower angles are placed two snap-hooks.

This jacket is put on before the administration of anæsthetic. When the patient is sufficiently under the influence, there is placed on the thigh, just above each knee, a pad with strap encircling the same, and the strap is fastened in the buckle, drawing it tight enough to be snug. Now catch the snap-hooks in one of the three rings on each strap, and the patient is ready for the operator.

The jacket is so cut that the tension comes as well on the back as over the shoulders and about the neck—in fact, less on the neck than elsewhere, and so does not interfere with respiration. The hooks can be unfastened and the limbs be extended in a few seconds time, should the patient behave badly under the anæsthetic. The pad that passes under the thigh being well cushioned, does not impede the circulation as would a piece of soft cloth or anything of that nature. The whole outfit can easily be carried in the obstetrical bag, and will often come in very handily in forceps operations.



The apparatus, as shown and described, was made for the writer by Messrs. Sharp and Smith, Chicago.

A NEW CHLOROFORM BOTTLE.

By F. OVERHOLT, M.D.,
OMAHA, NEB.

Some people are advocates of the "drop method" of giving chloroform. I mean by the "drop method," a continuous and regular precipitation of chloroform, a drop at a time, on to a thin cotton or linen mask, either

rapidly or slowly, as the judgment of the anæsthetizer thinks proper for the case in hand.

So far as I know, it is almost impossible to get chloroform from the so-called chloroform-droppers on the market, a drop at a time. The nearest approach to a dropper that would drop that came to my notice, prior to the present invention, was an ordinary bottle, with a cork having two notches opposite to one another, and that is seldom a success.

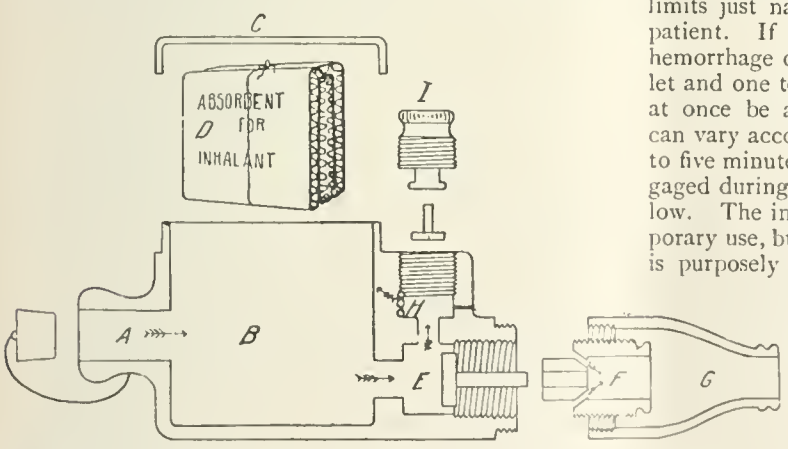
With this dropper one can have the chloroform a drop at a time either rapidly or slowly, depending on the amount of inclination given the bottle. It is impossible to get it "squirt by squirt;" it must always come a drop at a time. The dropper consists of a three-ounce bottle and a cork with two glass tubes in it, one a flow-tube, the other a vent-tube. The flow tube begins at the inner end of the cork, passes through it, is then drawn to a point, and turned down to a right angle. The vent-tube begins at the outer end of the cork, passes through it, and is bent and of such a length as to nearly reach the inside surface of the bottle at the bulge.

Now, numerous people have used the idea of two tubes, one flow and one vent; but, so far as I am aware, no one has packed the conical point of the flow-tube with cotton to regulate the flow. Herein lies the novelty and the success of this dropper, for by this means the chloroform can be made to flow to suit any purpose. I pack it so that with the chloroform just on a level with the flow, it will drop very slowly, say once every six to ten seconds; then, by tipping the bottle up, it will drop from sixty to one hundred and twenty a minute, which in my experience is as fast as is ever needed, provided the mask be thin and not covered with mucus or sputum.

The advantages are: 1, Anyone who can draw and bend glass tubing can make one in fifteen minutes; 2, it saves chloroform; and 3, it makes possible the giving of chloroform a drop at a time, the merits of which are not under discussion.

THE AIR-PRESSURE INHALER AND EXHALER.[1]

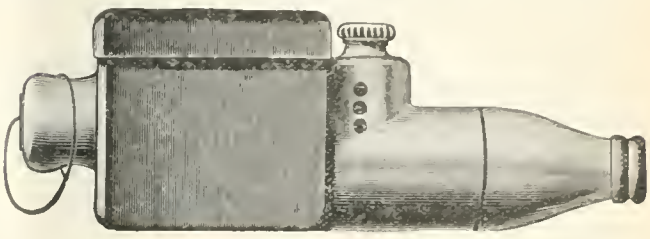
By CHARLES DENISON, A.M., M.D.,
DENVER, COL.
PROFESSOR DISEASES OF CHEST AND OF CLIMATOLOGY, MEDICAL COLLEGE UNIVERSITY, DENVER.



To fully describe its uses, the name of this new device should be the Adjustable Air pressure Expirator, Inspirator, and Inhaler, but a briefer title is preferred. The adjustable control of the air-pressure within the lungs is its chief merit, for both individuals and respiratory diseases are never exactly alike, and adjustability to the needs of each is a *sine qua non* of success in treatment.

The pathological changes which make different air-pressures within the lungs essential to the cure of chronic diseases, especially consumption, are very interesting, yet at the same time rather difficult to understand.

The chief element to be considered is what is called fibrosis, which is nature's means of healing, designed to



[1] Read before the Denver Medical Association, and Arapahoe County Medical Society, November, 1893.

bridge over, paste in, and protect the portions damaged by inflammation, mechanical injury, or the encroachments of tubercle bacilli or other germs. But nature, once started in her healing processes, is either too generous in her work, or, if unopposed by healthful lung exercise, overdoes the remedial part, and the fibrosis, which closes up the affected lung, becomes a most important factor of the disease. This consideration becomes a forcible argument when we recognize this fibroid process as nature's means of imprisoning, in the form of "tubercles," the germs of consumption; for it seems that only when so imprisoned, if not thrown off in the form of expectoration, are the tubercle bacilli kept from multiplication and re-infecting the system. It is quite probable that the pressure of this new fibroid growth upon these encapsuled germs renders them, for the time being, latent or unproductive of increase or further harm. But this process closes the affected lung, and starvation and poisoning of the blood must ensue from the resulting lack of oxygenation. On the other hand, when (keeping in mind the above hardening or shrinking process) we consider the mechanical conditions governing the ingress and egress of air in respiration, we are impressed with the utter uselessness of inhalations of medicines as ordinarily practised, except for diseases in the extreme upper air-tract. It is capable of demonstration that the inhaled air (which is usually thirty to ninety per cent. of saturation for the temperatures inhaled), ordinarily enters in the centre of the tubes, while the exhaled air comes out along the borders of the tubes, and that, too, from eighty-five to a hundred per cent. of saturation for the usually warmer temperature of the body. The result is that the medicaments, dust, etc., are caught by the heavier and moister out-going current, and the one tenth of the total air in the lungs—ordinarily exchanged for new air at each respiratory act—brings away more than its due proportion of the medicaments inhaled. Besides, if any medicine succeeds in passing on, it will not reach the diseased and shrunken portions, as intended, but must go with the constantly more and more diluted air containing it, to the more flexible and open healthy lung, where it is not wanted. That, then, which is desired is the thorough emptying of all the residual air possible, and then, after a full inspiration, such an increase of the tension of the contained air that the fibroid resistance will be gradually overcome, and the air inspired (only made germicidal to the extent that the healthy lung is not thereby injured), is forced into the diseased portions, especially in the out of-the way apices and protected parts. That, among other effects, is just what this little device is calculated to do and can nicely accomplish. Its mechanism is apparent from the following description, the accompanying cuts giving the actual size of the instrument, as made wholly of hard rubber by the Denver Surgical Instrument Company.

The air enters through the nozzle *A*, which is purposely made for the possible attachment of a rubber tube connected with an oxygen tank, any desired vaporizer or gas generator. Or, as is sometimes desirable with patients confined to the house, the breathing of the fresh cold out-door air can be had through a half-inch rubber tube, three or four feet long, connecting the inhaler therewith through a slightly opened window. In the box *B*, covered by the cap *C*, is some absorbent wool loosely wound, or, which is better, a coil of blotting-paper *D*, pressed like corrugated paper in form to suit, so as to be a little smaller than the inner calibre of the box. This serves as an absorbent to hold and gradually disseminate the various combinations of germicidal and healing oils, or other evaporating substances, which are intended to be used in this process.

There is an inlet valve at *E*, controlled by screw-head *F*, which can be reached by unscrewing from the instrument the mouth-piece *G*. This inlet valve closes with

expiration, so that the exhaled air goes off through the exit valve *H*, which in turn is made adjustable by screw-top *I*. This adjustable exit valve is the chief feature of this device. For ordinary use the inlet valve *E* needs to be from one-half to nine tenths open, while the exit valve *H* should only be from five tenths to one-tenth open; but there are a number of combinations which will be found to suit individual cases and diseased conditions. The tension of the air is increased at will, from an easy to a more difficult use of the instrument, according to the need and ability of the patient.

In known or suspected bacillary and fibroid disease of the lungs, *i e.*, in the various combinations of these processes which characterize the first stage of consumption, the needed thorough ventilation and cleansing (by the antiseptic inhalations) of all parts of the lungs can be accomplished by systematic practice of breathing with this instrument with the valves closed as nearly to the limits just named as can be comfortably borne by the patient. If there is pain, active inflammation, or recent hemorrhage or pleurisy, those limits (one-half for the inlet and one tenth open for the outlet valve) should not at once be attempted; and the times of practice, too, can vary according to the invalid's ability, usually three to five minutes out of each hour, when not otherwise engaged during the waking hours, being a good rule to follow. The inhaler is not intended for transient or temporary use, but for a permanent, continuous influence. It is purposely made small and compact, so as to be easily carried in the pocket, and ready for frequent inhalations and exhalations. The contracting and glueing up tendencies of affected air cells or tubes find constant and needed opposition in the proper use of this device. The medicine need not necessarily be renewed more than once a day, or it may be enlivened every little while by dropping a little alcohol on the absorbent in the box. The respirations, after emptying the lungs, should be *long, full inspirations through the inhaler, and then forcible expiration through the instrument, continued until the lungs are as nearly emptied as possible.*

When there are catarrhal softenings, excavations, or ulcerations, as well as where the use of the inhaler and expirator, as above described, causes pain, the limits named can be gradualty reached and at first the strength of the medicament lessened.

Uses in Chronic Lung Disease.—For uses in chronic lung disease, different combinations of some of the following have been experimented with and have proved very satisfactory. Menthol, phenosalyl, either the ol. pini

pumilionis, or ol. pini sylvestris, beechwood creosote (Merck's), tincture benzoin co.; oils of eucalyptus, cloves, cedar, and lupulin; mono-chlor-phenol, europhen, camphor-chloral, thymol, beta-naphthol, formalin, etc. The first three form a good basis for incorporating any of the other or like ingredients, and five to ten drops of the mixtures may be used in the inhaler once or twice each day.

For bronchitis a great variety of combinations of antispasmodics with anodynes and soothing essential oils (chloroform, ol. lupulin, ol. pini pumilionis, camphor, and acetic ether, etc.), will suggest themselves as beneficial, according to the nature and severity of the case; the probability of there being no fibroid complication rendering it less necessary to use a close exit valve. Three drops of sandal-wood oil to thirty minims of alcohol make a good inhaling mixture in some forms of bronchitis.

For asthma, in which inspiration is especially difficult, the adjustment of a free inlet and only a partly closed exit valve, with the use in the box of such antispasmodic, soothing, and relaxing agents as indicated, should be found very beneficial; while for emphysema, in which condition the relief of the over-distended air-cells is desired, a considerably closed inlet and wide open exit valve is indicated.

For angina pectoris, and allied affections, where such vaporizable substances as nitrite of amyl, etc., are indicated, it would hardly seem possible that a more convenient, economical, and suitable means of administering such remedies could be devised; for, shut up in the box, the vapors need be inhaled only so much as desired. One drop of nitrite of amyl to thirty minims of alcohol has been the strength of solution used.

The further possible uses of this new instrument, where antiseptic or germicidal vapors are needed to be held under control and inspired as indicated, are confidently left to abide the results of experiments which will probably be made as opportunities offer.

In the treatment of consumption, however, the author has found this method decidedly helpful to other means of treatment, favoring a desirable condition of asepsis in the lungs, cleansing and clearing out concealed diseased spots, increasing the ventilation of the affected lung, and augmenting, through the increased pressure produced, the process of hæmatosis.

"How is it, doctor, that I sleep so much better since the commencement of the treatment?" asked a lady with a considerable cavity and abundant fibroid protective material around it.

"Perhaps it is because you absorb so much more oxygen by using the inhaler," was the reply given.

This increased oxygenation and opening up of usable air-cells, when the instrument is properly used, is so different from the seeming closing up and suffocation effect of some other methods of treatment, especially of lately much vaunted "cures," so called, that one is compelled to conclude that any method of treatment must indeed be faulty which does not take into consideration the general fibroid contracting tendency in the healing lung. In some new cases their spirometrical and manometer records have been increased as much as twenty-five per cent. by one month's use of this inhaler.

An interesting test to show that the inhaled vapors, under forcible but impeded expiration, do reach the outermost parts of the lungs, can be tried by simply saturating the absorbent in the box with alcohol, and then freely using the inhaler as directed. One thus gets the full benefit of the stimulant diffused throughout his breathing-space. Through the operation of this forcible expiration he feels the muscular contraction of the diaphragm first, and then the restrained air in the lungs seems to be, as it undoubtedly is, driven successively into the periphery and apices. The somewhat reddened face of the experimenter indicates whether the force of the expiratory effort is sufficiently prolonged and powerful.

The hope is entertained that this little device may prove to be a valuable means of lung development in feeble-chested youths, the chief agency employed in the cure of very many chronic lung diseases and bronchial catarrhal affections, and to favor the arrest, more or less prolonged, of slowly progressing but advanced consumption.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 3, 1894.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	10	4
Scarlet fever	151	20
Cerebro-spinal meningitis	0	0
Measles	554	28
Diphtheria	197	58
Small-pox	22	4
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

A Healthy Spot.—The *Sacramento Bee*, criticising the California State Board of Health's Report, says that, according to this report, "August, 1893, was the healthiest month in the history of Los Angeles, the number of deaths being reported as '0,' with a population of 50,394. This beats the record of the world since the days of Adam. The population jumped about a little, too. From October, 1892, to and including January, 1893, the population is given at 65,000. In February there is a loss of 5,000, probably by immigration to Northern California, and in the next month, March, there is a gain of 5,000, probably of unfortunate emigrants from the East. This continues until August, when there is a loss of 14,606, the population having fallen to 50,394, but in the next month, September, the boomers got their work in and raised it to 65,000."

An Anti-coryzal Snuff.—M. Grellety recommends the following formula for a snuff to be employed against that common malady, a "cold in the head:" Betol, 2 gm., 50 ctgr.; menthol, 25 ctgr.; hydrochlorate of cocaine, 15 ctgr.; roasted coffee, 1 gm., 50 ctgr. Powder finely, and pass through a fine sieve. M. Jullien believes the best application to be vaseline associated with boric acid, and condemns all powders, which he accuses of bringing about the concretion of the muco-purulent discharge.

To Make Bed-pans Comfortable.—Make a pad of cotton cloth with any soft filling, eight inches square and one inch thick; to one side sew a piece of cotton cloth long enough to do the following: The pad should be placed on the posterior part of the pan on which the sacrum rests; then pass the cotton cloth band from the posterior edge of pan under the latter and forward to the prolongation in front, and fasten by passing the cloth over the latter, through a hole in its substance. This will hold the pad in place, while the latter contributes greatly to the patient's comfort.

What Young Girls Should Read.—A literary lady and member of Sorosis says that every young girl should read Naphey's "Physical Life of Woman," another book called "Tokology," and Cook's "Mothers and Daughters." This is dangerous advice. If we are not mistaken one of the above books is regarded as very untrustworthy and misleading. The safest way to teach girls what they should know is by personal instruction, with the help of a genuine and pure scientific text-book on anatomy and physiology.

THE USE OF SUGGESTION DURING HYPNOSIS OF THE FIRST DEGREE, AS A MEANS OF MODIFYING OR OF COMPLETELY ELIMINATING A FIXED IDEA.

BY RUSSELL STURGIS, M.D.,

BOSTON, MASS.

As the subject of this paper I have chosen a small field, but one of very great importance. The term "fixed idea ("idée fixe" of the French neurologists), I shall use hereafter as synonymous with "erroneous or worrying idea which has become fixed in the patient's mind, and which we intend to combat by means of suggestion." I shall endeavor to describe my idea of the mode of growth of a fixed idea, and to show, from analogy, that the idea implanted by hypnotic suggestion grows in the same manner. I shall report three cases in which hypnotism was used with success, to illustrate two methods of growth of a fixed idea, and shall mention another group of cases without reporting any one case, illustrating a third; and shall show analogous growth of the idea which was implanted with a view to modifying the effect of the fixed idea. I am convinced from experience that in this field—the use of suggestion to eliminate and modify a fixed idea—lies the future use of hypnotism in medical practice, and I am almost sure that, in cases not to be brought under the head of disturbances due to the presence of a fixed idea, the use of some other means of relief than hypnotism is advisable. To follow the probable method of growth of a fixed idea, it is necessary to imagine the thinking brain as divided into two parts, or strata: an upper, where ideas are at once recognized as the direct result of a stimulus from without, a stratum where conscious cerebration exists; a lower, or substratum (I shall use this word "substratum" to indicate this lower portion of the thinking brain when in future I refer to it), in which an idea may be implanted as the result of a stimulus from outside, without the brain being conscious of the implantation of the idea, or connecting the idea, in any way, with the stimulus from without. In the substratum, then, the idea is not recognized at the time of implantation, but after months or even years of activity in the substratum (during all this time its existence being unrecognized by the upper stratum), it obtrudes itself suddenly upon the consciousness of the upper division, growing more and more prominent until it becomes a fixed idea. I will later give my reasons for considering why the idea is constantly active, rather than dormant, during the time that it remains, though unperceived by consciousness, in the substratum. It is well to state here, that the time of implantation of a fixed idea in the substratum is, in many cases, coincident with some mental strain or shock, and that such strain or shock may be well nigh forgotten, until recalled by the intrusion of the fixed idea into the conscious upper stratum. In the well balanced mind, the fixed idea, after its entrance into the upper stratum, is held in check by other ideas, so that it does not grow at their expense; but in the unbalanced it may completely master other ideas and beliefs, until at last it stands out as the dominant idea of monomania.

The growth of the fixed idea may then start from the substratum. I shall cite Cases I. and II. as instances of this mode of growth. We all know that a comparatively trivial idea or belief, recognized at its inception as the result of a stimulus from without, may be so brooded upon and elaborated by the thinking brain, that it may become a fixed idea. This, then, is a second method of growth of the fixed idea, differing from the first in that it begins in the upper stratum. Such growth, as the result of a voluntary act on the patient's part, I will show in Case III.

On account of certain mental or physical peculiarities, inherited or not, a fixed idea may be implanted in either the substratum or the upper stratum, such idea taking the form of belief that the possessor of it has certain appetites or passions much in excess of the normal. I shall report a group of cases in support of this third theory of growth.

I will now cite various phenomena of hypnotism, to show that, as we can parallel the growth of the fixed idea through all its stages with the growth of the suggested idea through the same stages, the origin of both must be in the same part of the brain, namely, the substratum. I have never induced hypnosis beyond the first degree, that being the stage in which the patient is perfectly conscious of surroundings, and has on waking, memory of all that has taken place during the hypnotism. My reason for this is, that the suggestions made in that stage are sufficiently powerful for therapeutic use. As I have myself been hypnotized to this degree, I have personal knowledge of the subjective sensations while in that stage of hypnosis, and I am able to reassure my sometimes timid patients by giving them the result of my own experiences.

Now, let us consider the mental state of persons in the first degree of hypnosis, and let us follow the growth of a suggested idea. After the eyes are closed, the person at once, or in a very short time, passes into a state which I can no better describe than by likening it to the condition of a person who first wakes in the morning, before he is thoroughly aroused. There is a delicious sense of languor, and laziness is supreme. If it were suggested that the eyes could not be opened, the person would imagine that he could open them, but the effort to do so would appear to entail more trouble than would be worth while. No particular note of surroundings is taken, though the faintest noises are perceived. The suggestions now read from the paper, which were, in the waking state, most anxiously desired as a belief, convey little more meaning than a string of words. The person is too lazy to think seriously of anything, much less to note the implantation of the suggested idea. The part of the brain which when fully awake desired the belief, is now lethargic, or at least its power of perception is very much dulled. To what part, then, do we address the suggestion? On waking, the person says, "I heard you make the suggestion, but it produced no impression on me. Ought I to try to believe and to realize the suggestion now?" "No," I answer, "think nothing about it. Don't worry. The belief will come of itself." The person is hypnotized the next day, and perhaps on two or three successive days, the same main suggestion being made in exactly the same words, and still the person may think, even after the last sitting, that, much as he may desire, the suggested idea can never produce the belief which he seeks. In a week or more after the sittings have been discontinued, the belief begins to appear, gradually becoming more and more strong, until the

fixed idea vanishes. Here, then, is a growth analogous to the growth of a fixed idea which starts in the substratum. Step by step you can follow the analogy. Is it not more than probable that the suggested idea starts in the substratum? Constantly repeated to the patient on successive days during hypnosis; appearing in the upper stratum in a comparatively short time; are we not justified in thinking that the suggested idea, far from lying dormant, is at work all the time in the substratum, without the patient being aware of its presence there? Reasoning from analogy, therefore, we are right in assuming that a fixed idea does not lie dormant during the months or years that its activity in the substratum is unrecognized by the upper stratum.

Now, we can compare the growth of the fixed and of the suggested idea. The fixed idea is implanted in the substratum; the suggested, probably is. The suggested idea is constantly at work in the substratum, though unrecognized by the upper stratum; the same is probably true of the fixed. The fixed intrudes upon the upper stratum after months or years, and then begets a firm belief; the suggested intrudes after days or weeks, and very rapidly begets a firm belief. Can we explain the different length of time that the fixed and suggested ideas occupy the substratum, before they are recognized by the upper stratum? The fixed idea is not encouraged while in the substratum; belief in the suggested idea is ardently desired.

In cases in which the idea is implanted in the upper conscious stratum, and in which it becomes a fixed idea from the patient's constantly thinking of it, why should we hypnotize at all? Why not argue the patient out of the belief, applying our suggestion directly to the upper conscious stratum? Because, as the patient has spent many years, possibly, in fostering the growth of the fixed idea, we should have to present our suggested idea to the conscious brain for a length of time approximating that spent by the person in formulating the fixed idea, before we could make much of an impression—granting that we have the perfect confidence of our patient that our judgment is better than his. We therefore put this weary task upon the hypnotic suggestion to the substratum, well knowing that we shall get our result in a comparatively short time.

In regard to that class of cases in which the fixed idea may be the result of personal characteristics, the method of growth of the fixed idea is either that of class one, or of the class just mentioned; and the same is true of the growth of the suggested idea.

I will now give cases very briefly, reserving a more extended report for the conclusion of the paper.

Case I.—An unkind remark of a daughter to her father, followed by the death of her father the ensuing night, resulted in the realization, a year after her father's death, of the fixed idea that her father had died without forgiving her. This idea gradually grew, until it begot a remorse so strong that the woman feared for her reason, suffered from insomnia, and looked upon death as her only possible relief. The growth of the counter-suggestion can be traced, passing through exactly the same gradations of strength, until in a comparatively short space of time full realization of the belief suggested, removed the original worrying fixed idea. The suggestion was, "Your father has forgiven you," this being led up to by minor suggestions, fully reported, later.

Case II.—The fixed idea that the patient was responsible for an accident to her brother, appeared in the upper stratum *two years and a half* after the time of its probable implantation. Six months later, the idea had gained such power that the patient's general health began to suffer; nightly dreams of the accident, and optical illusions in regard to it by day, appeared.

In this case the main suggestion was, "You do not believe that you are responsible," etc. Troubles secondary to the fixed idea were the first to disappear. The main suggestion was first realized as a possible belief, five days after the first sitting, and became a firm belief at about the same time that the illusions completely vanished.

Case III.—This case is essentially different from the two preceding. The origin of the fixed idea was not in the substratum, but became one from conscious reiteration—the patient voluntarily allowing her mind to dwell on a certain idea of inferiority, as a sort of mental discipline. The ultimate result was the same in this case as in the others. The idea, under her fostering care, so grew that it became fixed, and brought as a result nothing approaching physical breakdown as in Cases I. and II., but simply acute unhappiness.

In Case III. we have a fixed idea as the result of constantly dwelling on the idea, for a given purpose. In Cases I. and II. it is probable that the idea which gave rise to the final belief was repeated over and over again in the substratum, where unconscious cerebration may exist, the person harboring the idea being unconscious even of its presence. These three cases have this trait in common: Iteration of an idea, resulting in the fixation of an idea, and establishment of a definite belief in consequence.

I have now traced a probable way in which a fixed idea may be implanted and may grow, and I have pointed out that continued presence of an idea in the substratum may be a sort of constant, though unrecognized, mental irritant, much as the constant reiteration of an idea may be. What rules are good to follow in hypnotizing, and what is a satisfactory method of framing the suggestion which is to benefit a given case?

Without going into details of the process of inducing hypnosis, let me here state, as I have stated above, that I never induce it beyond the first degree. I consider that for therapeutic use it is quite unnecessary to push the process farther. The responsibility, in all cases of hypnotism, I consider very great, and by advancing farther toward the unknown, we assume more and more unnecessary responsibility. If we can get results such as I describe, why should we not be content with the advantages that the first degree can give us? My experience goes to show that many and oft-repeated sittings are unnecessary. In Case I. but three were needed to efface remorse. In Case II. I employed seven. Fewer might have sufficed, as the suggested belief began to be realized after the fourth. In an incomplete case, now under observation, but not reported because not enough time has elapsed, three sittings have caused the belief to begin to "take." Now, as to suggestions.

1. We must find, if possible, the fixed idea, and frame a suggestion to combat it. This I call the main suggestion.

2. The suggestions should always be written out on a paper and submitted to the patient in the waking state, before he is hypnotized. This should be done that there may not be the slightest opportunity for either you or the patient to misunderstand the suggestion. You will then be sure that the suggestion will induce the belief that the patient desires. Never make a suggestion that is not on the paper, or which the patient does not thoroughly understand when in the waking state. If you desire to make a suggestion, even for the patient's good, which is not on the paper, and which he has therefore not seen with his own eyes, either wait till the next sitting or else wake the patient, write down the suggestion, show it to him, and then hypnotize him again. By closely following this rule, you run no danger that the patient will conclude that his will is not as strong as yours, a conclusion on his part which no honorable man will desire.

3. The main suggestion should be repeated over and over again, always using the same formula and words, to simulate the constant presence and iteration of the morbid fixed idea. I limit this statement to the main suggestion. Those that I call the subordinate suggestions, which are intended to remove symptoms that are the result of the fixed idea, may be varied as occasion may arise, but not unnecessarily. For instance, in Case II., in

regard to the optical illusions, the expression "which come against your will," was used after the first two sittings because the patient once, on waking, looked out of the window for the purpose of seeing whether the illusion would appear.

4. As the fixed idea is present, and as it probably was in the present tense, so to speak, when it was implanted, so the suggested idea must, if possible, be made in the present tense. Say "you believe," not "you will believe."

5. Where it is possible, I prefer not to attack the fixed idea directly. For instance, in a case that came to my notice, in which a person wanted to get rid of certain disagreeable reminiscences that worried him, the suggestion that the memories would no longer exist, probably accounted for failure. Memory probably cannot be abolished as easily as that. Make the suggestion, "the memories can no longer worry you," and the chances are that the suggestion will be received. I hypnotized a person for seasickness, which had always troubled her when going abroad, and which she expected to suffer on her next trip across the ocean, that was to be taken in a month. I suggested that she would not be seasick, but would make the most comfortable passage that she had ever made. The result was, that she apprehended no seasickness during that month, but the reality was painfully evident when the ship got well away from New York. A year or so after, some cases of the relief of seasickness were reported, in which the suggestion was made that a teaspoonful of water, taken when nausea first came on, would abort the attack. That was a good suggestion. Mine was faulty. This is a good example of what I call getting round a fixed idea, instead of trying to attack it directly.

6. Let your suggestion aim at bringing your patient to the normal. Suggest that an idea shall not worry a person any more than it would worry any normal brain. By following this rule you do not run any risk of implanting an idea that, if it should become a fixed one, could do your patient any harm.

It may well be asked how you can extract any notion of fixed idea in cases where, as in Case I., insomnia was at once relieved, and in cases which I called the third group, earlier in this paper. We all have had experience with cases of insomnia that have lasted more than a few nights. We know that the patient who comes to you for treatment is expecting to lie awake. We advise that the patient eat a light meal in the evening, go to bed at a certain time, and just before going to bed take a glass of milk. This slight change from his ordinary manner of passing the evening and going to bed, gives him a sort of expectation of sleep, and the chances are that he will get sleep that night. The idea is, "If something isn't done for me, I shall lie awake to night, just as I did last night." You suggest, during hypnosis, "You will sleep to-night," and you efface the fixed idea, which I grant is so weak that you can almost always induce sleep after a single sitting. In cases which are dependent upon mental or physical characteristics, the idea is, "I have stronger appetites or passions than most people." You implant the counter idea, "You have no more appetite or passion," or what not, "than the normal healthy man or woman," as the case may be. The result is that you can wipe out the excess, whatever it may be. I have now a case of nymphomania under observation. This woman says that she has not been so comfortable and happy for years, and she can't understand it. She was hypnotized three times only, not quite three weeks ago. This is clearly a case of suggestion tending to bring a patient to the normal.

Case I.—Woman, aged twenty-nine, single; typewriter and stenographer. Referred to me by Dr. M. H. Richardson, for insomnia. Patient was well nourished, but very nervous, with bright and restless eye. She gives a history of gradually increasing insomnia for the last five months. Has tried all the well known sedatives and hypnotics without effect. Has endeavored to tire herself out by hard work, has tried alcoholic stimulants as a means of inducing sleep, and is now convinced that she is to go insane unless she can procure relief. On inquiry I can find no cause for the insomnia. As nerve sedatives of various kinds had been tried without relief, it occurred to me that a strong nerve stimulant might be the best thing to use, and I prescribed a fairly large dose of strychnia, to be taken thrice daily, and told her to go home and to report to me the next day. Next day she reported to me that she had slept better than for a long time, having been asleep for four or five hours. She was ordered to keep on in the same way, and to report at the end of twenty-four hours. Next day she returned, and said that the insomnia was as bad as before, and insisted that something more should be done. Being convinced that the two doses of strychnia could not account for the sleep of the first night, I came to the conclusion that sleep was due to suggestion, she being aware that I intended treating her on quite different principles than any of her former advisers. I therefore proposed to hypnotize her. She consented with great reluctance, as she was afraid of what she called "an uncanny process." Thinking that there must be some mental trouble or worry causing the insomnia, I made the suggestion under hypnosis: "You will sleep to-night, and no mental worry that you may have had, can keep you awake." This was at four in the afternoon, and she remained with eyes closed till I waked her, at the end of eight minutes. I told her to go to bed at half-past nine that evening, and to report next day. She returned, and said that she had gone to sleep at ten, and had not waked till roused at half-past eight in the morning. I hypnotized her four times during the three succeeding days, with the result that sleep was induced as a habit. I saw her again at the end of a fortnight. She said that she slept very well, but that she was much troubled during the daytime. I asked her to tell me what it was that was troubling her, and with many tears she told me her story. Ten years before, her father was a wretched and very trying invalid. One night, after he had been particularly exacting, he remarked that no one seemed to care for him, and that the best thing he could do would be to die. She said that she agreed with him. He died that same night, without ever seeing her again. After his death, things went along smoothly, as far as she was concerned. About a year after his death she became suddenly aware that she had made a most unkind remark to him, and that he had died without ever having forgiven her. Gradually keen remorse followed this idea, which finally resulted in insomnia. Hypnotism had relieved the insomnia, but now the remorse was much worse during the day. She said that she could only be happy if she were dead. I asked how she expected to attain happiness if she were, and she answered that if she were dead she would see her father, and that she could explain to him how repentant she was, and that he would forgive her, which would make her happy. To determine if she were really sincere in this belief, I ridiculed the idea. I said, "Now, that is a most extraordinary belief; you can't be so foolish as to think that you will recognize him after death, or that he can recognize you after the lapse of ten years." She stuck to it that she believed it thoroughly, and begged me not to ridicule a belief which was her only source of consolation. "Well," said I, "there is only one more extraordinary belief, and that is, that your father can see into your heart, and that, knowing how repentant you are, he has forgiven you already." "Oh, doctor," said she, "if I only could believe that, I should indeed be happy." I told her I would suggest the belief during hypnosis. I hypnotized her on that day and on the two succeeding days, making the following suggestion: "You believe that your father can see into your heart, he knows your repentance, he has forgiven you, he is pleased to see you supporting your mother and sister." The belief came to her in less than three weeks. Ten months later, she writes: "I am asleep three minutes after my head

touches the pillow. Oh, doctor, I am so awfully happy!" Again she writes, later: "Life is so full of everything that is nice, and I get such pleasure out of it which a year and a half ago nothing on earth could have brought me!" To recapitulate: the fixed idea was, that her father had died without forgiving her. The corrective suggestion was in the form of a belief that her father knew of her repentance, and had therefore forgiven her.

Case II.—Woman, single, aged twenty-six. On October 19, 1889, she asked her brother to go to ride with her. The young man's horse fell with him, and the boy suffered a fracture of the base of the skull, from which he perfectly recovered in the course of time. In the spring of 1892 signs of a neurasthenic condition first developed. The young lady had digestive disturbances, amenorrhœa, neuralgias, and other symptoms of nervous derangement. Her general condition became so poor that in August she was put to bed for most of the day, and in December was put to bed entirely; being, however, removed from town in the early summer of 1893, and back again in the same fall. The attending physician spoke to me of the case in the early part of 1893. I advised him to find out, if possible, the underlying worry. In September, 1893, the lady told her physician that, synchronous with the development of nervous symptoms in the spring of 1892, there appeared the belief, which gradually became stronger and stronger, that she was directly responsible for the accident to her brother, because he would not have gone to ride had she not asked him. That she, shortly after the beginning of this belief, began to dream of the accident more and more frequently, until she dreamed of it every night, and that of late she saw her brother's bloody head between her and her book, if she attempted to read, or against the light, if she looked out of the window. The attending physician asked me, some time in November, to hypnotize the young lady. After considering the question very carefully, for I was afraid that there might be beginning mental degeneration, I told him that I would, and saw her for the first time on December 19, 1893. She lay in bed, moving restlessly, clasping and unclasping the hands, the face pale and anxious, the eyes with a peculiar expression. The nurse said that this was her usual condition, but that when she saw any of her young girl friends for a short time, as she occasionally did, she was able, by strong will power, to calm herself. I hypnotized the lady without difficulty, she being able to concentrate her mind upon the thought of sleep long enough to enable me to induce hypnosis. She remained, to the surprise of her physician and her nurse, perfectly quiet, with the exception of moving the fingers of her right hand once, till I roused her, at the end of ten minutes. I twice read from the paper these suggestions: "You believe that you are not responsible for the accident to your brother, and you will not worry about it any more." "You will not dream of the accident at night, and when you are awake you will not be troubled by visions of the accident." As soon as I aroused her, she at once looked out of the window, and I was sure that she saw a vision. She complained of a queer sensation in the head, as if she had been asleep at an odd hour of the day.

December 20th.—Had visions all the same yesterday afternoon, but the night was less disturbed by dreams. Hypnotized, and allowed to remain so for twenty minutes. When the patient was roused, she complained that she had been unable to move hand or foot.

December 21st.—Had fewer visions, but dreamed of the accident. Guard suggestions made at her request that no one but her physician can hypnotize her, and he only if she is willing. Guard suggestions as to following headache. "You will be untroubled by visions that come against your will, this afternoon and evening."

December 22d.—Dreamed of hypnotism. Says that she is very apt to dream of what is on her mind during the daytime. Saw no visions till nightfall, when, realizing that she had seen none since the morning, she saw a single one. Somewhat restless and uncomfortable yesterday afternoon on account of a cold that is coming on. Hypnosis twenty five minutes. "Perfectly comfortable and able to move." "If I were you I would not dream of hypnotism to-night."

December 23d.—Thought very little of hypnotism, and didn't dream of it at all. Has visions distinctly less than for some time hitherto. Suggestions seem to be in a fair way to "take." Has a bronchial attack which bothers her. Temperature, 101.5° F.; pulse, 110.

December 24th.—In much better bodily health to-day. More quiet and natural than she has yet appeared. No dreams of any sort last night. Visions even less distinct than yesterday. Has asked her mother to explain how it is that she is beginning to believe a statement made to her by a stranger when she is half asleep, which she has been unable to believe, though again and again repeated to her by those in whom she has confidence; showing that the first suggestion is beginning to be taken.

December 26th.—All the suggestions have taken. No dreams of the accident for five nights, nor hallucinations of vision all day yesterday. The lady's pulse having been rather high for a long time, thinking that it might perhaps be due to the nervous condition in which she has been, I decided to make this additional suggestion: "Now that you believe that you are not responsible for the accident to your brother, and as the dreams and visions have gone, your neuralgic pains dependent upon the nervous strain will disappear, and the pulse-rate, dependent upon the same cause, will become normal."

December 28th.—No dreams, very few and weak visions. Pulse down to 90 yesterday and the evening before.

December 30th.—Condition about the same. Pulse down to 80.

January 3, 1894.—Condition about the same, except that the visions are still weaker, and do not annoy her in the least. Pulse up again, perhaps due to expected menstruation, or to the fact that she walked half-way downstairs yesterday, the first time for over a year.

January 5th.—Visions almost gone. She is increasing rapidly in strength, and seems much better balanced than for a long time, though menstruation is now due.

January 7th.—Better in every way. Menstruation is overdue.

January 16th.—Not nervous as usual during menstruation, but noticeably quiet. Now goes downstairs every day to the parlor.

January 18th.—Wrote to her physician yesterday, saying that she was convinced that she had had nothing to do with the accident to her brother, and that she feels not the slightest responsibility for it. No dreams since the night of December 20th; no visions whatever now.

January 20th.—Went to see her uncle, who lives next door.

The fixed idea in this case was the sense of responsibility for the accident. There was no way to circumvent, so to speak, this idea—a contrary belief had to be implanted. This belief was implanted to bring the patient's method of thought back to the normal. The suggestion was repeated over and over again in the same words, and by reiteration it finally supplanted the morbid form of belief, and as a consequence of its implantation, probably, caused the secondary suggestions to be "taken" with great rapidity.

Case III.—Woman, single, aged twenty-seven; schoolteacher. This case had been under my care for a month or so before I ascertained the worrying fixed idea. She came to me one day, and asked me if I had had any experience with hypnotism. I told her that I had. She then asked me to hypnotize her, and to make the suggestion to her that she should cease to desire to see her own children. I naturally refused, and gave her my reasons, which were in the main, that if she should marry, that idea induced, might make her and her family very unhappy. She replied that she never could marry. Then came this history. She was early left an orphan. As she

grew up, she made up her mind that she must not be a burden to her brothers and sisters, and fitted herself for school teaching. She had been very fortunate in her chosen work, particularly among young children. She had been offered a very good position in the West, and had come to Boston to study certain subjects in which she considered herself deficient. For several years she had retired more and more into herself, and more and more had indulged herself in the morbid process of introspection and self depreciation, begun, as she said, as a mental discipline. She had been so successful in this "mental discipline," that she had fully persuaded herself that she was unattractive in person, a most erroneous idea, and that she had such a poorly equipped mind that no one could possibly care to see her, or talk to her. She considered that all her success in teaching was due to luck in getting just the right kind of children to teach. Being so unattractive, she had given up the idea that she could ever marry, though, for physiological reasons which she did not recognize, she was very anxious to have children of her own. She had doomed herself to old maidhood, and had the fear that as she grew older her love of children would leave her, thus excluding the only work that she could do, teaching. She was hypnotized on three successive days, once each day, April 1, 2 and 3, 1892.

Suggestions were made, some in the present tense, some in the future, as it seemed difficult to put them all in the present. Suggestions were as follows: "You will be happy because, 1st. You will, by associating with more people, recognize, better than in the past your own powers and attractions. 2d. You will be ambitious to make use of those gifts which in the past have made you so successful in your work. 3d. You realize that happy marriage is as likely to come to you as to any woman as young as you. 4th. Your love for children is inborn, and will last your lifetime."

April 16th.—Says that she has been to see various relatives and old friends in the neighborhood of Boston, and that their evident pleasure in seeing her has caused her to believe the first suggestion. She says that she believes the second and the fourth, but that she is as far as ever from believing the third. I have not yet ascertained at what time she began to believe the third; but she was married on July 21, 1893.

190 Marlboro' Street,

THE OPIUM HABIT IN CHILDREN.[1]

By LOUIS FISCHER, M.D.,

NEW YORK.

INSTRUCTOR IN DISEASES OF CHILDREN NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, PHYSICIAN TO THE MESSIAH HOME FOR CHILDREN, ATTENDING PHYSICIAN TO THE GERMAN POLIKLINIK (CHILDREN'S DEPARTMENT), BACTERIOLOGIST TO ST. MARK'S HOSPITAL, ETC.

During the last two years my attention has been directed to a series of symptoms which were in some instances obscure, and which did not justify the diagnosis made at the time. Having studied some of these cases since, I am convinced that we have more instances of children and infants addicted to the opium habit than we might otherwise suppose. As a matter of fact it is not only opium that is the cause of the mischief, but laudanum, paregoric, morphine and all the various alkaloids of gum opium. I will not mention the manner of introduction of this drug, which is so familiar to all practitioners of medicine, but would allude only to enemata of starch and opium hypodermics as the more common methods.

There is hardly a physician having experience with children who does not have to contend with ignorant mothers, stupid nurses, and careless women, who in order to get sleep at night feed their nurslings with soothing syrups, teething cordials, and other soothing liquids, not to mention the most common and also the most easily obtainable paregoric.

[1] Read before the Medical Society of the County of New York, January 22, 1894.

No one will deny that the soothing effect, and, if I may term it so, the stupefying effect, is caused by opium or its preparations. How can I prove it? Easily! Let us consider the following case:

Case I.—Child, Mary G——, three years of age, anæmic; poorly nourished as regards fatty and muscular development; no history of cough or any other previous disease. Family history excellent; no tuberculosis, lues, epilepsy, or rheumatism. Was attacked with diarrhœa on July 7, 1892, owing to faulty diet and hot weather. The child was under various treatments until July 20th, or about two weeks. When I first saw her I found that she had received a chalk mixture, a bismuth mixture, various powders, and her fourth physician gave her starch and laudanum enemata. The latter was most efficacious.

I irrigated the child's stomach with an ordinary flexible catheter attached to a fountain syringe, using the table salt solution which is so well known. I ordered barley gruel, and gave directions to discontinue all medicine. For thirst I ordered some boiled water, acidulated with dilute hydrochloric or phosphoric acid. This was done in the babies' wards of the Post-Graduate Hospital and child sent home. Case was seen next day. Diarrhœa continued. I ordered an irrigation through a rectal tube as high into the colon as possible, with plain hot water, followed by cooled water, using enough water till washings were clear. The case was seen every day for ten days, the diarrhœa continuing. The child was put on salicyl. of bismuth, gr. iij., every two hours, and did not return for twenty-two days. Its mother had meanwhile consulted her former physician, who had previously ordered gtt. x. laudanum in starch water and was told to again give this same dose, but she had to increase the quantity until gtt. xvj. were used. The child's mother assured me that the injection acted like magic, for, to quote her own words, the "appetite returned, the child slept after each injection, and the diarrhœa stopped." I was told, however, that it was necessary to give two injections daily, each containing sixteen drops of laudanum (not diluted); in the commencement she gave gtt. iij., increased the dose drop by drop until the child received ten drops for each dose. The child seemed to get flabby and fat, gained considerable weight, but required an enormous amount of sleep. The pupils were constantly contracted—at times enormously dilated; pulse slow, very full, 68 during the condition of constipation, or soon after the effect of the laudanum injections. At other times, or when the drug was withheld, diarrhœa was the most constant and prominent symptom; pulse irregular, very much accelerated, at times 146 and more; pupils widely dilated; excessive irritability, restlessness, insomnia; vomiting a frequent symptom, more especially bilious in character. Reflexes at patella and plantar surfaces were greatly exaggerated, at times *vice versa*. Skin assumed an almost icteric appearance and frequent diaphoresis was present.

The child was again lost sight of, and I was sent for about March, 1893. Found it in a semi-comatose condition, greatly emaciated and icteric; conjunctivæ deeply pigmented. Child gradually sank, and died about April 5th.

The urine was examined microscopically and no evidence of disease found, and only an excess of phosphate. No eruption nor swollen spleen to diagnose typhoid: no temperature at any time beyond 99° F. in the rectum. A peculiar point was that, although the child was in an apparently deep coma, on talking to her she could always be aroused and gave coherent answers to questions by her mother or myself.

Post-mortem examination showed a very emaciated body generally; no evidence of disease in heart or lungs. Spleen normal in size and texture. Stomach normal; contained some mucus and bile. Gall-bladder pervious, the bile-ducts somewhat occluded, liver otherwise normal. Intestines showed evidence of inflammation, congestion, no ulceration, nor visible change at Peyer's patches. No

distinct evidence of disease in gastro-intestinal tract. Brain normal; arteries showed no change. Kidneys normal; no evidence of tuberculosis. From constant tenesmus intra vitam, slight prolapsus ani et recti.

No distinct pathological change justified a positive diagnosis excepting that of opium-poisoning.

The above clinical picture will warrant, I believe, the study of our cases, for since that time I have found twenty-two such ones. One physician told me he had seen five or six cases, and being a prominent pediatrist I can fully rely on his diagnosis. One of my cases was a child whose mother was a confirmed opium-smoker, and the child, after weaning, was also addicted to its use.

In Ringer's "Therapeutics" we find (page 425, 11th edition) that the active principles of opium pass out with milk and hence a nursling can be affected thereby. If a mother is addicted to opium, nursing her offspring would be contra-indicated.

Case II.—Child, six years of age, had always been delicate, family history excellent. Three years ago was first attacked with swollen joints, evidently, from history, polyarthritis rheumatica. Since that time was infected by a child in same house with varicella, later had bronchitis, and about one year ago pertussis, which was neglected until severe gastric symptoms appeared and child expectorated blood from force of the coughing paroxysms. *Status præsens*, May 5, 1893: Child has hernia of one week's standing—not noticed before—cough, no temperature, neck emaciated, anorexia, insomnia, occasional diarrhœa. Restless, irritable, when excited seems to have fainting spells, formerly had convulsions. Mother says child is quiet, and that cough and diarrhœa subside only when paregoric is given; formerly gave two teaspoonfuls every hour; now, after one-half year of its use, gives sometimes two tablespoonfuls every hour, and even more. Child's pupils were constantly contracted and seemed dull; semicomatose most of the time. Child can always be roused although in apparent deep sleep; mother laid stress on the slowness of respiration; frequent perspiration.

I watched the child for ten days, gave a placebo; meanwhile there was a terrible diarrhœa at times; gastric irritability appeared as nausea, rarely vomiting, eructations, and persistent singultus. I ordered bromide of potassium and chloral hydrate, giving five grains of each every two hours; gave bismuth, salicylate, and resorcine, starch enemata, rice and barley diet; gave claret and port wine, and ordered a hot bath at night to induce sleep. The symptoms gradually subsided, excepting diarrhœa, insomnia, and singultus. To test my diagnosis, on May 27th, or twenty-two days after first seeing the child, I gave five drops of laudanum in water, and had almost a complete cessation of all symptoms.

It is proper to state that faradization and massage were tried, but with no apparent effect on the singultus or nausea. Child's mother was informed of the true state of affairs, and although she promised to withhold the paregoric, I found that the child's apparent improvement indicated a continuation of same. Child was very icteric, and gradually sank and died in August. No autopsy allowed.

Case III.—Abraham B——, well-nourished boy, four years of age; no previous contagious disease, had never had gastro enteric disease, was nursed about fifteen months; teeth regular, speaks clearly; no history of rheumatism, tuberculosis, nor lues. Was first taken sick in March with diarrhœa after eating some ice-cream; continued ill for over three weeks; was not attended by a physician, simply taken to a neighboring pharmacist for treatment. Child's enteritis relapsed, mother believes, because he drank some beer; this time very persistent tenesmus, and on finding the lower bowel protruding through anus consulted a physician. Child had passed considerable blood in each stool. He received careful dieting and also some suppositories, the ingredients of which I do not know. Mother says that child's diarrhœa subsided after using the second box of these suppositories. Child continued to improve, and did not again consult her physician. Through some dietetic error the child had diarrhœa at various times; she had the suppositories renewed and inserted one every four hours. Not finding any benefit from same, used one every two hours, and later one every hour, until she found that the child's bowels were so loose that she was obliged to use them all the time.

Child was brought to me in September, with a history of pre-existing diarrhœa of one-half year's standing. I found him well nourished but having diarrhœal symptoms with an occasional gastric complication.

No apparent disturbance of nervous system existed, nor was insomnia very well marked; slightly irritable; no apparent change in pupils; skin normal in texture; conjunctival mucous membrane not pigmented; no temperature; pulse, 86; respiration, about 23 to 25; no diaphoresis. Gave placebo and observed about one week. Mother reported child much worse. I ordered small doses of pulv. Doveri and calomel, and found child greatly benefited. This continued until I suddenly discontinued pulv. Doveri and gave acid. muriatic. dil. Diarrhœa at once reappeared. Gave chloral at night, hot-baths, ordered constipating diet, gave iron and cinchona, and by using argent. nitric. in suppositories gradually had symptoms subside. I ordered Tokay wine and also some claret containing tannin. The treatment was persisted in for over two months. Child was finally discharged, cured, but now (five weeks after) is still under observation.

Case IV.—Infant, eleven months old. Mother has the opium habit; has now three other children, all healthy. Child has four teeth, emaciated, looks thin, is very restless, irritable, cannot talk a single syllable; has several spots on each limb, looking like purpura hæmorrhagica, has a large nævus on its back; has been troubled with constipation since birth—mother is also constipated—vomits frequently, usually after receiving its bottle. Baby receives Robinson's patent barley, and at other times condensed milk and water in the bottle when mother is sick. No temperature. Mother has just weaned it, and finds great difficulty with its bowels. Gave baby some extract of opium, which she bought from a Chinese merchant, to control the diarrhœa. On weighing the quantity at a drug store the usual dose given was about one-half grain of extract of pure opium.

Has done this now for about two weeks—mother is not sure, possibly sixteen or seventeen days. She now tells me that unless she continues the pills the child cries, can't sleep, and has diarrhœa. On examination no distinct pathological condition can be found, no temperature, no tenderness, some tympanites, some nausea, but almost constantly ten to fifteen stools a day or in twenty-four hours. Stools are green, rather offensive, contain mucus, no blood. On giving five drops of laudanum in starch no apparent improvement is noticed, but on giving eight drops in starch enema baby is more quiet, diarrhœa less, and nausea apparently better.

Treatment.—Child was put on a stimulating diet, enemata of starch with yolk of egg, and brandy or Tokay wine alternately; beef-juice, clam-broth, chicken-broth, peptonized milk. For thirst, brandy and water and phosphoric acid, teaspoonful to a tumblerful of sweetened water, *ad libitum;* to tone up the nervous system, mild faradization, massage over spine, and a cold douche morning and evening. Bromide of potash was tried, and in every case discontinued, owing to relapse of diarrhœa from its use, at least partly so; chloral hydrate, sulphonal, chloralamid were tried, hot bath before retiring. Elix. of quinine, iron, and strychnine was used.

One important point which gave me more benefit was that my patients being all children could not of themselves secure opium or its preparations, as they were not old enough to know their ailment, and hence I attribute the cure of many of my cases to this one fact.

Again, in one case much mischief was done, because, as the mother put it, "she could not see her child suffer," and gave several doses of paregoric at night and when her child was exceedingly restless. It did not take long for

the child to have a subnormal temperature and *exitus lethalis*.

In looking over the literature of this subject I found absolutely nothing relating to children. Strümpell describes emaciation, anæmia, tremor, insomnia, as the most important symptoms, also gastro-enteric disturbances.

Dr. Houchard[1] found persistent albuminuria in ten cases, using morphine (adults), which eventually terminated in anæmia. He believes—

1. That it is caused by its specific action on the medullary centres.

2. By being consecutive to paresis of the renal vasomotor supply.

3. That anomalies of pressure are capable of producing renal disease.

Dr. Houchard asserts that morphine rapidly decreases arterial tension.

Dr. Haig[2] disagrees with the latter views about albuminuria associated with low tension pulse.

Both are apparently correct, for in diabetics who are taking large doses of opium there is increased tension of the pulse followed by decreased tension. The question to be determined is whether the albuminuria is caused by high or low tension.

Erlenmeyer says that children born of women addicted to the morphine habit are practically morphine-eaters at birth.

During the first few days of life, unless morphine is given to them, they are apt to suffer collapse, and their condition may end in death, the child being too weak to withstand the violent symptoms, which are similar to those which follow the sudden withdrawal of the drug in adult opium *habituées*.

In the beginning of my paper I referred to nurses who, in order to sleep, do not care to be troubled by a child, and who in most instances administer anything to quiet it. Since then I have found a very good woman who never retired without a bottle of whiskey under her pillow, to soothe the child if it awoke. In the same manner paregoric was occasionally administered, not to do harm but to do good.

To recapitulate the drugs which served me best in the sudden and gradual weaning from opium I found sulphonal to promote sleep, overcome restlessness, monobromide of camphor (from 0.2 to 0.5 gm.) followed by (0.5 to 1.0) gm. of sulphonal, and sodium and bromide of potassium and chloral. Hot baths at night. Lupuline at night.

Chloralamid 0.5 to 1.0 gm. at night. Nutrient enemata, consisting of starch, wine, egg, and beef-tea and brandy. In all twenty-two cases were seen and attended, nineteen of which recovered. Several of these are still under observation, but show absolutely no symptoms excepting irritability and nervous twitchings resembling chorea minor, and in one there is persistent albuminuria.

Three cases proved fatal, and these were very carefully attended and nursed. No means were spared to save life. In some the same treatment was pursued, being guided by the urgency of the symptoms demanding the most immediate relief.

There is no doubt in my mind that a great many cases which die, more especially in summer, and which are treated and diagnosed as cases of marasmus, atrophy, athrepsia, and general debility are possibly cases of opium-poisoning simulating the latter diseases, and simulating more especially that most common summer complaint or gastro enteritis catarrhalis acuta et chronica.

To sum up, the symptoms which were noticed as almost constant were :

1. Diarrhœa, very severe at times, which was watery, foul-smelling, rarely containing blood excepting where severe tenesmus existed. In one of my cases prolapsus ani and recti occurred.

2. Vomiting occasionally, not a constant factor.

3. Anorexia in all cases.

4. Insomnia in all cases.

5. Urine scanty, in some very concentrated, containing excess of phosphates.

6. Skin in beginning normal ; occasionally diaphoresis ; rarely pigmented.

7. Late in the course of the disease always icterus.

8. Reflexes very much exaggerated at times ; no reaction at other times.

9. Constant irritability, nervousness, and restlessness.

10. Pulse usually full, slow, regular, later in the disease very much accelerated and irregular.

11. Heart's action corresponded with the pulse ; heart-sounds distinct at all times.

12. Pulse in the commencement of the disease varied from 68 to 79, in the later stages of the disease as much as 140 to 146 per minute.

13. Respiration, deep, slow, at times 18 to 24 per minute in beginning, 28 to 62 and more in later stages of the disease.

14. Stupor almost constant, at times deep coma ; patient could be easily aroused and spoke coherently.

15. Incontinence of urine—enuresis nocturna et diurna.

16. Itching, or a condition of formication, must exist, judging by the continued scratching and the small eczematous eruption found over most of the body, more especially the arms and legs.

17. Urine usually high-colored, frequently albuminous and very scanty.

If I have succeeded in directing attention to a very common disorder, which is not referred to in a single text-book on the diseases of children, then I will have accomplished the object of this paper.

A Word for the Sleepless.—Dr. J. E. Huxley, of Maidstone, Eng., thinks he has hit upon the natural remedy for sleeplessness. It is in brief to curl under the clothes like a kitten, or put the head under the wing like a hen. His detailed description of the technique is given in a letter to the *Medical Press and Circular*, when he says : "This insomnia seems to be now a universal affliction. We live wrongly ; sit up late and overwork the brain, and then go to bed in an excited condition. No one seems to have hit upon the natural remedy. I think I have. People take chloral and the like at their peril, and the fatal consequence not seldom ensues. It is all wrong, for you cannot control the dose required for the exact circumstances. But try Nature's plan instead—lower the supply of oxygen to the blood—produce a little asphyxia, limit the quantity of air to the lungs, and the heart and circulation becoming quicker, the brain loses its stimulant, and sleep follows. When you find yourself 'in' for a sleepless night, cover your head with the bed-clothes and breathe and rebreathe only the respired air. Thus you may reduce the stimulating oxygen and fall asleep. There is no danger. When asleep you are sure to disturb the coverings and get as much fresh air as you require, or, when once drowsiness has been produced, it is easy to go on sleeping, though the air be fresh. What do the cat and dog when they prepare to sleep? They turn round (generally three times) and lastly bury their noses in some soft hollow in their hair or fur, and 'off' they go. They are in no danger, although it might look as if they were from the closeness with which they embed their noses."

PERMANGANATE OF POTASSIUM AS AN ANTIDOTE FOR MORPHINE.

By WILLIAM MOOR, M.D.,

PHYSICIAN TO THE WEST SIDE GERMAN CLINIC; MEMBER OF THE NEW YORK COUNTY MEDICAL ASSOCIATION.

In offering to the profession a new antidote for morphine it is not my desire to speak of a new, heretofore unknown or unused chemical body; on the contrary, the substance which forms the subject of these lines is one with which every physician and pharmacist is familiar. The term "new antidote" simply relates to the fact that the substance in question had not previously been used for the purpose of antagonizing or, rather, destroying morphine, for I don't know of a single instance in which permanganate of potassium—$Mn_2O_8K_2$—has been used as an antidote for morphine.

I have paid a good deal of attention to the therapeutics of permanganate of potassium during the past year, thinking that such a powerful destroyer of organic matter should be more utilized in the treatment of certain gastric disorders that are associated with putrid fermentation of the ingesta, also in cases of cancer of the stomach to suppress the fœtor of the breath, which renders patients a burden to their surroundings, and came to the conclusion that its mode of administration was at fault, inasmuch as no one likes to drink a purple, "poisonous" looking liquid, and, on the other hand, if given in pill form, it would act as a caustic upon a very small part of the glandular lining of the stomach, thus causing distress without any beneficial result. After some trials I found that the best way of administering it was to have it made up in pills with cacao butter and talcum or kaolin, and to direct the patient to drink very slowly a glassful of water just one minute after taking the pill, for the latter begins to disintegrate in one minute at the temperature of the body. By using this method I successfully combated the extremely disagreeable odor in a case of cancer of the stomach. About that time I treated a well-known actor suffering from acute pleurisy. This gentleman was addicted to morphine, and as I had taken much interest in him I earnestly sought the best plan to break his habit. The idea occurred to me that perhaps permanganate of potash might decompose morphine, the latter being an organic substance, and that by making use of a certain method I could eventually break his habit without restricting him from taking his morphine. My patient, however, started on a professional tour just when I began to put my idea to a test. This circumstance did not prevent me from continuing my researches as to the effect of permanganate of potassium on morphine, and to day I am permitted to offer to the profession what I consider to be the antidote "par excellence" for morphine.

In the following remarks I shall give a brief outline of the experiments that led me to this conviction. Pouring a solution of one grain (0.06 gramme) of $Mn_2O_8K_2$ to one ounce of water (31 c.c.) into a solution of one grain of sulphate of morphine to one ounce of water, I noticed that this mixture did not for an instant assume the purple color of a $Mn_2O_8K_2$ solution, but at once formed a greenish liquid; and that after a few moments a dark precipitate would sink to the bottom of the test-tube, leaving an almost colorless, tasteless liquid, in which the presence of morphine could not be detected. Knowing my great susceptibility to even very small doses of morphine, I could easily ascertain whether or not this colorless, tasteless liquid possessed any narcotic qualities. The road of safety being the best way, I began by taking a mixture of one sixth of a grain of sulphate of morphine and one ounce of a 1 to 2,000 $Mn_2O_8K_2$ solution. Under ordinary circumstances one-sixth of a grain of morphine has a profound narcotic effect on me, lasting for several hours; I, therefore, rarely have taken for analgesic purposes more than one-eighth of a grain. The above-mentioned mixture of one-sixth of a grain of sulphate of morphine and one ounce of a 1 to 2,000 $Mn_2O_8K_2$ solution produced no effect whatever on me. Gradually I increased the amount of morphine, and correspondingly the amount of permanganate of potassium, until I took two grains of the sulphate of morphine in one dose with the same amount of permanganate of potassium in solution. The results of these experiments, however, did not demonstrate that permanganate of potassium was an antidote to morphine, as it was quite possible that it might be deoxidized by the organic matter of the buccal cavity, œsophagus, and stomach, chiefly by the contents of the stomach, before it could act on the morphine. To gain certitude on this point I conducted a series of experiments, a synopsis of which is as follows:

1. A 1 to 2,000 solution of permanganate of potassium in water was held in the mouth for fully five minutes, when it still had a dark red appearance, approaching the characteristic deep purple color of a $Mn_2O_8K_2$ solution, although the tongue and the gums have become brown.

2. If we dissolve one drachm (4 c.c.) of the white of egg in one ounce (31 c.c.) of water and to this add one drachm of a 1 to 250 solution of permanganate of potassium in water (one-fourth grain of $Mn_2O_8K_2$), the mixture will for a moment have a purplish color, and after stirring it for one minute will be of a reddish-brown color, and have a distinct taste of permanganate of potassium. After five minutes, on filling two test-tubes with this mixture and adding to one of them a small quantity of sulphate of morphine—this latter being an energetic deoxidizer of $Mn_2O_8K_2$—but adding nothing to the mixture in the other test tube, the former mixture will at once become of a much lighter color (light amber) than the one without morphine. Even after thirty minutes this differentiation can be effected. Thus we see that it takes one drachm of the white of egg at least thirty minutes to completely deoxidize one quarter of a grain of the permanganate. Now, I found that one-quarter of a grain of permanganate will be deoxidized by exactly the same amount of sulphate of morphine in one second—for the sake of convenient calculation one moment may be considered as one second—therefore one drachm of sulphate of morphine deoxidizes one-quarter of a grain of the permanganate at least seventy-two thousand times quicker than a drachm of albumen would do it, assuming that the latter could accomplish it in five minutes. But as we saw that the deoxidization was not complete after the elapse of half an hour, we are justified in saying that the chemical reaction between the permanganate and the salt of morphine is infinitely more rapid than the one between the former and the white of egg.

3. By substituting for the albumin one drachm of peptone, in the experiment just related, we find that one grain of $Mn_2O_8K_2$ is not completely deoxidized by one drachm of peptone in five minutes. Calculating in the same manner as before we come to the conclusion that the rapidity of reaction between the permanganate and the salt of morphine is at least eighteen thousand times greater than the one between the former and pepton.

Having gained the knowledge of these facts it is not surprising that I could swallow with impunity toxic doses of sulphate of morphine followed in a few moments by a corresponding amount of the chemical body which I was justified to consider the antidote par excellence for morphine. Thus, on one occasion, four hours after a full dinner, at a time when the stomach must have contained a great amount of soluble peptones and other organic matter, I took two grains of the sulphate of morphine in about half of an ounce of water, followed in one minute by three grains of its antidote—for safety's sake one grain more than necessary—dissolved in four ounces of water. In another instance, on January 9th of this year, three hours after a light supper, I took, in the presence of several colleagues belonging to the staff of the West Side German Clinic of this city, three grains of sulphate of morphine, followed in about thirty seconds by four grains of permanganate of potassium, both in aqueous solution. I was perfectly confident that the antidote possessed such a wonderful affinity for the morphine that it would select it instantaneously from among the contents of the stomach,

and thus render harmless what might have easily been a fatal quantity to one so susceptible as I am to even very small doses of this alkaloid. A striking demonstration of the astonishing selective faculty of $Mn_2O_5K_2$ for morphine can be shown by mixing two hundred and fifty grains of the white of egg with one ounce of water, dissolving in this mixture one grain of sulphate of morphine and adding to the whole just one grain of the permanganate dissolved in one ounce of water. After thoroughly mixing not a trace of morphine can be detected; which conclusively proves that the molecules of the antidote instantaneously selected the molecules of morphine without being interfered with by the albumin, though the quantity of the latter so greatly exceeded the quantity of morphine.

The question arises, What becomes of $Mn_2O_5K_2$ and $C_{17}H_{19}NO_2 + H_2O$ (morphine) after they have reacted upon each other? While it is easy to determine that the permanganate is deoxidized by the morphine with formation of manganese binoxide—MnO_2—manganate of potassium—$MnKO_4$—and potassium hydroxide—KHO—thus leaving O_2 for the oxidation of morphine, this latter undergoes changes, the nature of which I have not yet been able to determine, but hope to be able to do so in the near future.

In case of poisoning by any of the salts of morphia, ten or fifteen grains of the antidote dissolved in six or eight ounces of water should be administered at once and repeated at intervals of thirty minutes three or four times, or even more often. Permanganate of potassium, as well as the salts of manganese, are comparatively harmless even if given in large quantities. I have poured into the stomach of a rabbit weighing four pounds a solution of five grains of $Mn_2O_5K_2$ in two ounces of water, and one hour later two grains more dissolved in one ounce of water, without noticing any toxic effects whatever. One ounce of the sulphate of manganous oxide has caused only brisk catharsis (Dr. Thompson).

In cases of poisoning by the alkaloid itself or by tincture of opium (laudanum), also by opium, it is advisable to acidulate the antidotal solution with diluted sulphuric acid, or in the absence of this with some white vinegar (not red vinegar), by which the insoluble morphia will be at once converted into the soluble sulphate or acetate.

I have strong reason to believe that the administration of permanganate will be of beneficial effect even after absorption of the morphine has taken place. This statement I base on the following:

Professor Edward Hitzig,[1] of Halle, two years ago, proved beyond a doubt that morphine which was injected subcutaneously into dogs was secreted by the glandular lining of the stomach. Hitzig succeeded, by washing out the stomachs of animals that had received morphine subcutaneously, in obtaining fully one-half of the injected amount during the first hour after the injection. It is therefore a logical necessity that an antidote which acts instantaneously must destroy in the stomach a certain amount of poison that got into the circulation either through hypodermatic injection or through absorption by the stomach, for it is evident that the same circulation which conveys a poison from the peripheral parts of the body to the stomach, must also bring back to the latter a part of the poison which previously was absorbed by it. I intend to carry out a series of experiments upon animals to prove this conclusion; for the present I just state that some experiments for this purpose upon rabbits have been highly encouraging. As to the effect of permanganate of potassium upon other alkaloids, I shall briefly enumerate the results I have obtained.

Atropine.—One grain of sulphate of atropine dissolved in one ounce of water added to one grain of permanganate of potassium in half an ounce of water. Color, purple, as if the solution contained only permanganate of potassium. After four hours, color still purple, no change from original permanganate color; one drop instilled into a person's eyes widely dilates the pupils in a few moments; midriasis lasting over twenty-four hours. After eight hours, color dark red, taste intensely bitter; addition of sulphate of morphine gives the characteristic reaction (dark precipitate, colorless liquid above it). After twenty hours, color dark brown, taste intensely bitter; addition of morphine gives the characteristic reaction. Thus permanganate of potassium has practically no effect upon atropine.

Cocaine.—One grain of cocaine muriat. to one ounce of water added to one grain of permanganate of potassium in half an ounce of water. Color, purple, as if the solution contained only $Mn_2O_5K_2$.

Four hours later, color dark red, taste intensely bitter; one drop instilled into a person's eye causes decided midriasis lasting half an hour; addition of morphine gives the characteristic reaction. Eight hours later, color grayish red, taste bitter; applied to the pharynx distinct difficulty in swallowing noticeable; dark precipitate on the addition of morphine.

Practically no effect on cocaine.

Veratrine.—Two grains of veratrine muriat. to half an ounce of water added to two grains of permanganate of potassium in one ounce of water. Color, purple. Ten minutes later, purplish red. Fifteen minutes later, dark brown; precipitate on addition of acetate of morphine. Thirty-five minutes later, precipitate with brownish liquid above, the latter turning light on the addition of acetate of morphine, and if applied to the nasal mucous membrane causing violent sneezing (one of the characteristics of veratrine). Useless in veratrine poisoning.

Pilocarpine.—Two grains of pilocarpine muriat. to two ounces of water added to two grains of permanganate of potassium in one ounce of water. Color, purple; after five minutes, still purple; after forty minutes, carmine.

After seventy minutes, color carmine; one drachm injected subcutaneously into a rabbit causes lachrymation, salivation, profuse perspiration, irregular rapid breathing (160), three or four copious watery discharges.

After three hours, color still red; addition of morphine gives the usual reaction. Practically without effect on pilocarpine.

Aconitia.—Two grains of aconitine to two ounces of water + two grains of permanganate of potassium to one ounce of water. Color, purple. After stirring for two minutes, same color.

After two hours, color unchanged; half a drachm (2 c.c.) injected into a full grown rabbit; animal restless in a few moments, turns his head to the side, makes rapid swallowing motions, salivates, is evidently nauseated; difficult, irregular breathing, tremor, opisthotonos; animal lies on its side, apparently "in extremis," but after ninety minutes symptoms begin to abate.

After twenty-four hours, color still reddish purple. Dark precipitate by addition of morphine. No effect on aconitine.

Strychnine.—One grain of strychn. sulphat. to one ounce of water + one grain of permanganate of potassium to half an ounce of water. Color, purple; after five minutes, red; after fifteen minutes, dark brown, intensely bitter; after thirty minutes, same color, taste intensely bitter. Addition of morphine, black precipitate, colorless liquid above.

Could not be depended upon in strychnine poisoning, if the stomach should contain organic matter, which is the rule.

I now submit this paper to the unprejudiced criticism of the profession, and hope that my confrères will aid me in developing the ideas laid down in it. If my humble efforts should result in saving human lives, I should feel amply rewarded.

ACCOUCHEMENT FORCÉ.[1]

By S. MARX, M.D.,

NEW YORK.

When, about a year ago, I read a paper[2] reporting a few cases in which I had performed Dührssen's operation of deep cervical incisions, I ventured to remark at that time that the field for this operation was extremely limited; thus, indicated in cases of threatened death of the mother or the fœtus, when the condition of the os does not admit of rapid delivery by other methods; for example: A severe uræmic convulsion followed by a rapidly deepening coma, rupture of the uterus, accidental hemorrhage, and so forth. While looking for an operation, on the one hand, less radical and heroic in selected cases than the Duhrssen's operation, and, on the other hand, speedier of result and more reliable of action than the ordinary methods now in vogue, such as the Kiwish, Krause's, the modern elective accouchement forcé was brought prominently forward by Grandin. It must become evident to every fair-minded observer that any operation which in a great many cases can be made a purely elective one, is the one to be chosen. This is the one great advantage in doing this operation. It thus simulates any other operation for the performance of which the operator selects the time most suitable to himself, selects assistants, prepares his instruments and his patient, and brings every known scientific principle to bear in one direction, viz., the safety of the mother and her unborn child. Furthermore, the accoucheur knows that there will be no uncertainty or failure of action, as sometimes happens when the catheter is used to provoke labor. We know that the uterus of a woman who is uræmic is particularly tolerant to any measure by which we hope to start up pains; and, are we not sometimes disappointed when the catheter fails to provoke pains even at the end of thirty-six or forty eight hours? Again, there is no foreign body to be introduced and left in the uterine cavity by which sepsis might be introduced; further, the integrity of the membranes, so often endangered by other methods, is preserved, and serves a very useful purpose in the delivering of these women. When once the actual steps of the operation are begun, there is no postponing; the uterus is dilated, and the child delivered in one séance. Further, the hand is the only instrument actually used in operating; that it is an instrument of precision no one will deny, and that a substitute for the hand has never been found in any instrument, no matter how skilfully or scientifically made.

Mode of Operating.—The operation divides itself into two stages: the preparatory stage and the operative stage. The first stage may in some cases be omitted. Such cases are where the cervix is dilatable and the lower uterine segment already merged; or where the os is soft, non-resisting, and boggy, as occurs in placenta prævia. Therefore, it is especially in this complication that the operation is indicated and most easily done. The elective operation having been decided upon, the patient is placed on the back, no anæsthetic being necessary. After thorough asepticism of the vagina, cervical canal, and external genitals, a Sims' speculum is introduced, and the anterior or posterior lip is seized by bullet forceps. Iodoform gauze cut in strips the width of two fingers is carried, in the grasp of a Garrigues intra-uterine tampon forceps, into the cervical canal; slowly and gently worming your way until the gauze is well in the canal or until it meets a resistance, which is the presenting fœtal pole, and most frequently the head. The canal is then tamponed as completely as possible. The vaginal vault and vagina are tamponed in the ordinary way, and the patient put to bed. This method of tamponing the cervix is very important, and I lay especial stress upon this point. It has for its object, 1, that it mechanically separates the membranes without endangering their integrity; 2, it materially softens the os and causes a marked disappearance of the portio; 3, it provokes uterine pains, and sometimes gives rise to sufficient uterine action to cause the woman to deliver herself, as occurred in one of my cases.

In the cases I have done the preparatory tamponade upon, the patients have all complained of intermittent crampy pains, indicative of uterine action. In from ten to fifteen hours the tampon is removed, the patient thoroughly douched and an anæsthetic given, and the second or operative stage commenced. The os is now found very soft and dilatable, so as to admit readily one or two fingers. The hand, introduced into the vagina one finger after the other, is gently inserted until the open hand can be introduced. The hand, then closed, is gently withdrawn. If rapidly withdrawn it is easy to imagine how readily the uterus might be ruptured. The closed hand acts similarly to the ballon bags of Tarnier, which are introduced empty into the uterus, inflated, and then gently withdrawn. After withdrawing the fist several times and no resistance on the part of the cervix being encountered, the os is then dilated 10 ctm. (according to the width of my own hand) and dilated sufficiently for the passage of any ordinary child. The membranes having been preserved, a Hicks's version, if indicated, is easily done, and the labor terminated. The uterine tampon, in the absence of hemorrhage or sepsis, is entirely optional with the operator. The cases I wish to present are five in number.

Case I.—Complete placenta prævia in the eighth month. Mrs. O——, multipara, eight months pregnant. Symptoms for the last two months indicative of placenta prævia. For twenty-four hours prior to my seeing the case with the attending physician there was almost constant sharp bleeding, for which she had been thoroughly tamponed. On examination, a deeply bilaterally lacerated cervix admits two fingers. Supra-vaginal portion a quarter of an inch in depth. Complete placenta prævia. Separation on the left side. Child alive, head presenting. On account of the great loss of blood, and in the face of a grave complication, accouchement forcé decided upon. In the regular way, the fingers gradually worked up through the left-sided detachment, and the os gradually and fully dilated. The bleeding being very severe and finding the detachment of the placenta nearly complete, thus threatening also the vitality of the child, I delivered as rapidly as possible. A Hicks's version done, membranes ruptured, and a living child speedily delivered, immediately followed by the placenta, which had in the meantime completely detached itself. Uterus contracted well, but owing to the presence of a cervical tear involving probably the circular vessel, the bleeding continued. Three silkworm sutures passed. Bleeding ceased; convalescence normal. The cervical tear I attribute solely to the rapid delivery I was forced to make. It does not militate, in my opinion, against the value of operation. Deep tears have occurred and will occur in labors apparently normal. Cervices have been torn from uteri. They have been mashed and bruised by forceps thoroughly and carefully used. But I will admit it should not have occurred; but in the presence of such a grave complication where the result was so favorable to mother and child I did not deem it of much moment. To have left the woman alone, to have tamponed her, thus trusting blindly to the power of nature, what would have been the result? Certainly a dead child, most likely a dead woman. Primary trachelorraphy is an easy operation. I will concede that if one attempts to sew up a cervix post partem in the depths of the pelvis in Sims's position it proves a most difficult and awkward operation. But if the lacerated cervix be seized by bullet forceps, pulled through the vulva, as it were, into the world, the operation becomes one of the simplest imaginable.

Case II.—Mrs. L. M——. In the ninth month of pregnancy, when the membranes suddenly ruptured with the discharge of liquor amnii. Very slight pains present. Sent for her physician, who invited me to see the case.

[1] Read before Section on Obstetrics, New York Academy of Medicine, December 28, 1893.

[2] Read before the County Medical Association, February, 1893.

On examination os admitted easily one finger. Small segment of supra vaginal portion present. The entire vagina filled with umbilical cord, beating very weak, at times slowly, then irregularly. Presentation, deflected head not in truly transverse position. Indication, fœtal exhaustion, and accouchement forcé decided upon. Operation easily done. Delivery of living child; convalescence normal.

Case III.—Mrs. B——. Old, primipara. At the end of pregnancy, when pains set in with the rupture of amniotic sac. Has been seen, and in charge of two physicians for forty eight hours. All this time pains severe and regular. No progress taking place, I saw the patient and found the os thin, hard, and admitting one finger; for which chloral, quinine, hot douches, and morphia were given. No progress in spite of hard pains. Chloroform did not affect the os. The following morning pains begin to fail; uterine inertia. Mother's pulse rapid. Parturiens looks bad; commencing maternal exhaustion. Os still in the same condition. An accouchement forcé done, and in one hour os slowly and fully dilated. Head engaged, position, L. O. P. Forceps tried and failed. An attempt to rotate the head was then made and failed, for while rotation was easily accomplished, it would instantly re-rotate when the hand was removed. Internal version then performed. Partial extension of head. Forceps to after-coming head. Living child delivered. Weight, eleven and three-quarters pounds. Circumference of head, fourteen and a half inches. Convalescence normal.

Case IV.—Mrs. R——, aged twenty-four. First pregnancy interrupted by nature at five and a half months during an attack of eclampsia. Is now pregnant about six and a half months, when I take charge of the case. Urine nearly suppressed. Albumin twenty-five per cent. volume. No casts found. No œdema. Patient nearly blind. Double vision present, due probably to an abducens paralysis; retina free from changes; ocular examination undertaken by Dr. E. Meirhof. Intense headache, epigastric pain; high tension, pulse at 130 per minute; vomiting. Medical treatment, including veratrum, nitroglycerine, hot baths, Croton oil, does not ameliorate condition, but seems to aggravate the symptoms. Accouchement forcé decided upon for the following morning. Preliminary tampon after thorough antisepsis; severe crampy pains during the night; circulatory tension in the meantime relieved by veratrum. Following morning, the tampon having been removed, the os is found soft, and readily admits two fingers. Slight labor pains present; in the regular way os is dilated. Hicks's version performed, and a living premature child born; lived two hours; uterus tamponed with iodoform gauze; condition of patient good; during the night the patient complains of great oppression and gradually merges into a condition of extreme prostration. Pulse 160, soft and very feeble. After a critical examination of the patient, a diagnosis by exclusion is made of an acute iodoform poisoning. Gauze removed; intra-uterine douche of a Thiersch solution given. The symptoms gradually disappear and the convalescence runs a normal course.

Case V.—Mrs. L——. Threatened uræmic convulsions. Primipara. Pregnant six months; history very similar to the one above related. Pulse of extreme high tension, due as much probably to the administration of continuous doses of digitalis as to the threatened uræmia. Accouchement forcé decided upon, and counselled the operation for the next morning. In the meantime, after thorough douching, the lower uterine segment and vagina tamponed, and veratrum ordered. In this case the mere tamponing of the lower uterine segment was sufficient to provoke such pains during the night that the patient delivered herself in a short time of the tampon and a dead premature child. Convalescence normal.

In closing I beg to state that I did not come this evening to praise the operation as one to be universally recommended; for there are cases, and these not few, where the method cannot be used; such cases where from repeated and old lacerations the cervix is reduced to a mass of dense cicatricial tissue. Such a case I reported last year where no amount of physical energy could overcome the constriction caused by an old cicatrix, nothing short of a bloody dilatation by the knife would answer. The cases as above related are but a presentation of cold facts; they were all, with but one exception, seen in consultation; they were not selected cases. The method was faithfully tried upon women as the indications happened to present themselves. The rate of mortality is practically *nil*. All the women recovered; of the children, the two deaths occurred in children non viable. The case which presented the fairest and squarest test as to the value of the operation was Case I., that of complete placenta prævia. The woman lived on the top floor of an east-side tenement, surrounded by all the filth, squalor, and poverty that one could possibly imagine. Antisepsis and asepsis, surgically speaking, were utterly out of the question. Yet in spite of all these hindrances, face to face with as grave an obstetric complication as one has to meet, this woman was delivered in about three quarters of an hour by the accouchement forcé, her ruptured cervix sewn up, and still the object of the operation was attained—a living mother, a smooth convalescence, and last but not least, a living child.

Clinical Department.

SPERMATORRHŒA.

By C. WAECHTER, M.D.,

NEW YORK.

Our text-books teach us that this disease is quite a rarity, and for the most part exists in the imagination of patients. This opinion is, I believe, shared likewise by most men of our profession. If the term "spermatorrhœa" be understood as meaning a more or less continuous flow of spermatic fluid, I must also share the foregoing belief, for, although I have treated quite a considerable number of patients with diseases of the genito-urinary system during the last twenty one years, still I have not as yet seen a single case of true spermatorrhœa. All cases reporting a continuous flow of semen proved to be those of hyper-secretion of the prostatic and other glands.

In the course of my experience I have found quite frequently that patients suffering from chronic prostatitis are losing semen during the act of micturition, especially when at defecation (a condition which must be denoted as spermatorrhœa). I have continually quite a number of cases under treatment, and do not find such of rare occurrence.

Some time ago I examined men of various ages, and with healthy urethral canals, as to the possibility of losing semen during micturition. The urine of fifteen persons at different times, especially during defecation, was examined, without finding spermatozoa in any case. It was, by the way, no easy matter to find persons with healthy prostates.

In regard to the correct diagnosis, I consider it important to examine the urine collected during defecation and filter it; the moist deposit or residue upon the filter is placed upon an object glass and diluted with a watery solution of glycerine. If spermatozoa are found the ordinary urine of different times is examined in like manner. It is a good rule to examine the urine—if spermatorrhœa is suspected—several times, as semen cannot be detected in every specimen.

Those cases in which the ordinary urine (*i.e.*, without defecation) contains semen, show generally aggravated symptoms, and are more difficult to cure. But there are exceptions. It is remarkable how some men are able to endure the unnatural loss of semen without any harm. I have treated, for example, married men who had no

doubt been suffering for years from spermatorrhœa, without being weak or impotent. Still, in other cases, even a slight loss of semen produces quite considerable disturbances.

The causes of spermatorrhœa are: Gonorrhœa, strictures, masturbation, etc. Those cases depending upon diseases of the cord and brain are not within the scope of this paper. I only wish to mention that it is probable that, in some cases of tabes dorsalis, spermatorrhœa is an important etiological factor. If the prostate be diseased for any continuous length of time, we have as the result an extended inflammation of the ductus ejaculatorius and seminal vesicles, which furthermore may reach the spermatic cord and testicle. As in other inflamed organs, we find congestion, hyperæmia, and swelling resulting in tissue alteration.

Chronic gonorrhœa is frequently the cause of spermatorrhœa; generally the seat of the former is the pars prostatica; with the bulb-sound we find it, as a rule, painful, swollen, and difficult of penetration. The examination per rectum shows the prostate generally also enlarged, sensitive, and painful. The endoscope reveals hyperæmia, erosions, ulcerations, and granulations around the caput gallinaginis.

It is a well-known fact that many cases of chronic gonorrhœa are generally obstinate to cure. According to my experience the cause is, that spermatorrhœa is frequently present at the same time; the loss of semen is keeping up a continuous inflammation of the prostate, hence the cure of such cases is difficult.

In cases of stricture we mostly find the posterior part of the canal involved, and consequently loss of semen takes place.

Masturbation will bring on inflammation of the urethra and produce not alone spermatorrhœa, but also considerable disturbances of the organism, especially that of the brain and spinal cord. The frequent weakening emissions and their consequent depression of spirits, generally cause these patients to seek medical aid and advice. This mental depression is often increased by reading the announcements of quacks.

Diseases of the rectum and bladder may bring on spermatorrhœa by producing prostatitis.

In my opinion it is doubtful if chronic constipation can produce spermatorrhœa, provided the urethra be healthy. I have examined the urine of quite a number of such patients without finding spermatozoa, but if chronic prostatitis exists at the same time, seminal fluid can be frequently detected. In such cases constipation produces loss of semen, and the latter again—through the inhibition of the peristaltic motion—constipation. The "non-emission" is also of evil consequence.

The sequelæ of spermatorrhœa are of various kinds. The nervous system especially suffers. The most frequent complaints are spinal irritation—weakness in the lumbar region of the spinal cord, radiating pains and weakness of the lower extremities, depression of spirits, melancholia, loss of memory, want of desire for mental or physical exercise, restlessness, want of refreshing sleep, ideas of suicide, etc.

The heart's action is altered in some instances; we may find palpitation, and accelerated pulse. The organs of digestion are likewise frequently impaired; tongue coated, appetite decreased, pressure and fulness in the region of the stomach, flatulence, continual constipation, hemorrhoids. The micturition is generally frequent and painful, while the urine contains in some cases mucus or pus.

The results of spermatorrhœa are weakening of the sexual organs, incomplete erections, and premature emissions; in advanced cases, impotency.

The prognosis of spermatorrhœa is favorable. There are also stubborn cases needing long treatment. At times there are relapses, especially if the local treatment had not been of sufficiently long duration. It is advisable to examine the urine after the cure has been completed.

The treatment is constitutional and local. Locally I prefer the nitrate of silver, and begin with a very weak solution ($\frac{1}{16}$ or $\frac{1}{8}$ grain to the ounce), in order to lessen first the sensibility of the mucous membrane, and to prevent if possible any untoward reaction from the prostate and bladder. Each succeeding injection is gradually increased in strength, until finally forty or sixty grains to the ounce are reached. These injections are made first every one or two days, later every three or five days. The instrument devised by myself and described in the MEDICAL RECORD, August 6, 1892, has proven to be perfect. We are able with it to cauterize the pars prostatica alone, so that the patient is able to bear strong solutions without much pain.

In stubborn cases I use also the negative pole of the constant current to the caput gallinaginis. Regarding the constitutional treatment, hydrotherapy is of considerable importance and benefit. By its means we are able to tone up the nervous system, to improve the digestive organs, and to alter the circulation. For this purpose sweat-baths of brief duration, with douches, are to be used, also packs, cold frictions, sitz baths, electricity, and massage, according to the indications. The cool or cold douche produces a powerful stimulating effect, and is best used after having warmed the body previously in the sweating box or hot room. The sitz-baths will quiet the irritation produced by the injection. They are first used lukewarm, later on cooler. The wet packs will quiet the nervous system and afford rest to the irritated brain and spine. Electricity I use in the form of electric baths. The diet and habits are regulated. Internally mineral waters and tonics are given, according to indications.

In conclusion, I take the liberty of giving the histories of a few cases for illustration.

CASE I.—I. M——, aged twenty-eight, consulted me regarding dyspeptic symptoms. He complained of loss of appetite, eructations, and pressure after each meal, distention of stomach, and obstinate constipation. In consequence he felt weak bodily and mentally. His head seemed dull and loss of memory was considerable. Family history good, as a child well, masturbation for several years. Pollutions frequent. Married since one year, is able to have coition but once a week, feels weak in the back after it for one day. Examination: lungs and heart normal, stomach and abdomen considerably distended, pressure produces pain. Tongue coated. The introduction of the bulb-sound evinced sensitiveness, especially at the prostatic portion. The rectum was also sensitive and the prostate enlarged. The urine voided during defecation contained many small spermatozoa, at other times none, besides mucus and phosphates.

Diagnosis: Catarrh of the stomach and intestines, spermatorrhœa, sexual neurasthenia.

Treatment: Introduction of elastic bougies (later sounds) as far as the neck of the bladder; deep injection of nitrate of silver, one-sixteenth grain to the ounce, thereupon sitz-baths of 85° F. for twelve minutes, with a weak faradic current. After reaching four grains to the ounce I used every second day the above-mentioned instrument, in order to cauterize the prostatic portion alone, until I reached forty-five grains to the ounce.

The remaining treatment was as follows: mornings, cold ablutions; twice weekly, short sweat-baths with cool douches; massage, cool rectal injections, wet bandage over the stomach during the night. The diet was restricted to light digestible food. Internally: muriatic acid with pepsin, later elix. ferri phosphor., c. quinii et strych. Improvement was quite rapid, appetite and strength increased. Patient was discharged cured after three months.

CASE II.—C. D——, aged twenty-six, of healthy appearance, acquired gonorrhœa three years ago which in spite of all treatment still persists. In the morning the well known suspicious drop is to be seen; during the day the meatus is moist.

The pars prostatica is very sensitive. The urine collected during defecation contains numerous spermatozoa, also pus and mucus, no albumin.

Diagnosis: chronic gonorrhœa, spermatorrhœa, cystitis. Treatment: irrigation with kal. hyperman. solution, then lukewarm water and nitrate of silver, sounds, sitz-baths, one sweat bath weekly, washing out the bladder with boracic and salicylic acid, later instillation of nitrate of silver one to two per cent. Internally: Buffalo-lithia water, ol. santalin, milk diet. After six weeks the discharge had ceased, no more spermatic elements, urine clear. At the close of the treatment I operated for an existing phymosis. Duration of treatment, ten weeks. (The accompanying spermatorrhœa was perhaps the reason that the disease was not arrested earlier.)

Case III.—W. S——, aged twenty-five, tall, strongly built, always well in childhood. When twenty years of age acquired syphilis; inunction treatment, kal. iod. sweat-baths. Three years ago gonorrhœa lasting six months. Since this time frequent pollutions, producing weakness, mental depression, and often ideas of suicide. A water cure taken two years ago from Pastor Kneipps, resulted only in a temporary relief. Sleep restless, not refreshing, appetite fair, eructation, heartburn, constipation. In the act of coition, ejaculations came prematurely.

Examination: Considerable hyperæsthesia of the urethra, especially pars prostatica. The urine (taken during defecation) contains quite a number of small spermatozoa, uric acid in abundance.

Diagnosis: Spermatorrhœa, sexual neurasthenia.

Treatment: Injection of nitrate of silver, sounds, sitz-baths, electric baths, mixed current, wet packs, morning cold washing (clyster) daily. The improvement was but slow, in consequence of a frequent interruption of treatment necessitated by travel. Six months elapsed before a cure was obtained.

Case IV.—M. P——, aged thirty-two; anæmic; weak; as a child has always been well; masturbation for years; acknowledges having led quite a dissolute life. His nervous system is shattered and he can hardly endure any noise; buzzing and weakness of the head; sleep restless. Weakness in the loins, cord, and lower extremities. Patient has been impotent for the last three years, no erections, frequent pollutions, increasing the sense of general debility. Appetite is poor; flatulence; obstinate constipation; painful hemorrhoids. The entire urethra is very sensitive, the prostate enlarged. The urine, as generally voided during the day, and that during defecation, contains a considerable number of minute spermatic elements, also a large amount of uric acid.

Diagnosis: Spermatorrhœa; impotency.

Treatment: Injection of nitrate of silver, with sitz baths; sweat-baths of short duration, with douches; central galvanization; general faradization; massage, Swedish gymnastics; at night wet bandage over the stomach; rectal irrigation. The diet was regulated. Internally: Bilin-water, muriatic acid with pepsin later. Elix. ferr. phosphor. comp. with extr. damian.

The patient's condition improved gradually, although after two months there still persisted a loss of semen during defecation, so that I also made use of the negative pole to the caput gallinaginis. At the close of four months' treatment the patient's condition had improved considerably, he was able to enjoy intercourse, but the ejaculations still came too soon. I advised a sojourn in the mountains.

Case V.—C. W——, aged thirty-six; of healthy physique, but from a nervous family; has suffered for two years from nervousness and depression of spirits, gradually increasing and alternating melancholia and excitement. He has taken a good deal of bromide, chloral hydrate, etc. The cause of his trouble is unknown to him, he is married very happily and has no financial cares. At night he hears voices in his or the next room (hallucinations), he awakens his wife, and she explains to him his deceptions. Sleep very restless, feels tired in the morning; appetite poor; frequent acid eructations and constipation. During the last few weeks has suffered from rheumatic pains in various muscles. Patient had practised coition frequently when younger; at present he feels less power.

The urethra, especially the prostatic portion, is very sensitive. The urine (taken during defecation) contains a great many spermatozoa, besides a large amount of uric acid.

Diagnosis: Spermatorrhœa, neurasthenia.

Treatment: Injections of nitrate of silver, sounds, sitz-baths, light sweat-baths, wet packs, electric baths. Mornings: cold ablution, enema. Internally: Carlsbad and Bilin-waters. After four weeks' treatment there was but little improvement; patient persisted in the idea that his brain was affected and that he would become insane. In consequence I requested a consultation with Dr. G. W. Jacobi. The latter agreed in diagnosis and treatment, and advised, besides, opium in increasing doses. As the result of the consultation the patient became more quiet; also the opium, continued for two weeks, had a beneficial effect. The improvement went on steadily, and after four months' treatment I advised a sojourn in Germany and Switzerland, from which he returned improved in every respect.

After W—— had been pursuing his daily occupation for several months he again became nervous and his sleep was restless. An examination of the urine revealed a relapse of the spermatorrhœa. In consequence strong injections were made twice weekly of argent. nitr., and light sweat-baths were continued for two months. One year has elapsed and patient has enjoyed the best of health.

The above cases seem to me sufficient. The aim of this article is to draw attention to the relative frequency and importance of spermatorrhœa.

220 East Tenth Street.

A CASE OF EXTENSIVE PLEURITIC ADHESIONS.

By FRANK WARNER, M.D.,

Lecturer on Operative Surgery, Starling Medical College, Columbus, O.

A very instructive and interesting case of extensive pleuritic adhesions, resulting from a stab wound, recently came before the Board of United States Pension Examining Surgeons, of which I am a member.

It was interesting in that such extensive adhesions, combined with so greatly a thickened pleura, are infrequently seen. Instructive from the fact that it illustrates how closely a thickened pleural membrane, adherent so as to prevent the proper expansion of the chest, will yield many physical signs of a pleuritic effusion or a consolidated lung.

Five years ago the man received a stab wound in the right anterior fourth intercostal space, which penetrated the pleural cavity and some of the lung-tissue. An inflammation followed which involved the entire right pleura; extensive exudations of lymph evidently occurred, and a complete adhesion of the pleural surfaces from top to bottom. It is true, there is nothing very unusual for the entire membrane to become involved in a pleurisy, or for the whole surfaces to become glued together, the one to the other. This latter condition we frequently see in post mortems held for other reasons than in the search of the lungs or its membranes. But what is not common in the case is the excessive amount of lymph deposit, which has subsequently undergone more or less organization, resulting in an almost complete fixation of the affected side of the chest, and yielding physical signs that would be perhaps misleading unless we stopped to consider the pathological conditions present.

The right chest remains almost completely fixed during inspiration and expiration. The supra-clavicular spaces are unequal; the right being depressed. The af-

fected side is much contracted. Percussion yields a flatness over the entire right lung. Auscultation shows vesicular murmur abolished, except slightly at apex front and back of the lung in question, and here greatly enfeebled. Changing the applicant's position and posture alters in no way the physical signs. The same flatness and absence of murmur remain. The ribs of the right side are packed closely together as a result of the contraction of the walls of the chest. On the left there are the usual signs of increased vesicular murmur, etc., where one lung is required to do extra service.

This flatness on percussion is the result of excessive thickening of the pleural membrane, for the inflammatory process extended over several months; and when a sero-fibrinous process continues any great length of time the pleura is apt to become very greatly thickened. As Loomis observes, p. 175 in his "Practice:" "This pathological process may be completed in two weeks, or a sero-fibrinous deposit may not be absorbed for months, and then the pleuritic thickening becomes very extensive."

Naturally the flatness on percussion, conjoined with negative symptoms of consolidation of lung-tissue, suggested an effusion. But the intercostal spaces of the affected side were not bulging as in an extensive effusion, but contracted. The affected side measured less by two inches than the normal side; the reverse being true in an effusion. The ribs were much closer together on the diseased side than the healthy side; which is just the opposite in a decided effusion. The tests relating to the change of position have already been spoken of. Vocal fremitus was lessened, but not abolished, as it usually is in an effusion.

There was no cough nor expectoration. The patient was well nourished; and the condition of the liver, spleen, stomach, intestines, and kidneys normal. The heart, both in structure and action, was normal.

The case illustrates that a thickened pleura may, and perhaps is, sometimes mistaken for either a pleuritic effusion or a hepatized lung.

SUBCUTANEOUS LIGATURE FOR VARICOCELE WITH AN ORDINARY NEEDLE.

By ERNEST F. TUCKER, M.D.,

PORTLAND, ORE.

NEVER having seen the following procedure described in any of the text-books or journals, and having made use of it several times myself and shown it to others, I think it might be of interest to some of the readers of the MEDICAL RECORD, if they are not already familiar with its performance.

An ordinary stout needle, about two inches long, and the necessary ligatures are all the instruments required. The needle, threaded, is made to pierce the scrotum from before backward, between the vas deferens and the veins, one end of the ligature being drawn clear through. The eye-end of the needle, which is still on the thread, is reintroduced through the hole of exit, and carrying the thread with it is made to pass outside of the veins and under the dartos, and out again through the hole of entrance, this end of the ligature drawn through, the needle unthreaded, and the ligature tied.

By thus using the blunt end of an ordinary needle to carry the ligature back about the veins, there is no danger of piercing a vein or of puckering the skin of the scrotum included accidentally in the ligature. It does away with the necessity of Reverdin's needle or any of its modifications, thereby diminishing the chances of sepsis, which are necessarily attached to the use of any mechanical needle, and adding to the general simplicity of the operation.

In all other particulars the operation should be performed as described by Dr. Keyes.

Bellevue Hospital has more patients than beds to put them in.

Progress of Medical Science.

Catarrh of the Biliary Ducts.—Dr. Castaneda Gonzalo has studied three hundred cases of affections of this nature, which are common in men from twenty to forty years of age, and almost always secondary and chronic. There is generally pain about the gall-bladder, extending sometimes to the back, and sometimes there is jaundice. The increasing size of gall-bladder is a pathognomonic sign of the disease, which may last months and years. To empty the bladder will settle any doubt about the diagnosis, which it is important to make from an etiological and anatomical standpoint. Treatment should be causal. Chronic gastritis is cured by milk diet and calomel; opium and nux vomica modify favorably the gastro-intestinal catarrh of alcoholics. Simonillo (an indigenous plant, *Lœnneccia parvifolia*, Compositæ) is valuable as a eupeptic and cholagogue. A successful treatment is artificial or manual emptying of the gall-bladder, or the "Jimenéz manœuvre," as it is called—a national invention, almost unknown in Europe; it overcomes obstruction, alleviates pain, and verifies the diagnosis.—*Universal Medical Journal.*

The Dangers of Overfeeding in Children.—Dr. Bellot calls attention to the frequency of disturbances due to overfeeding, not only in infants at the breast, but also in those who are older and take ordinary food. (*New York Medical Journal.*) He has made a study of these disturbances as they affect the digestive canal, the liver and the kidneys, the locomotor apparatus, the skin, and the nervous system. It is not sufficiently recognized, he says, that hepatic colic is apt to attack overfed children, especially those who live in cities, and therefore lead a sedentary life not very favorable to the combustion of fatty food. Although less frequent than in adults, hepatic colic is not positively rare in children. Rouisson found concretions in the biliary passages of the new-born, and Hein observed hepatic colic in a child twenty-five days of age. Undoubtedly heredity and a sedentary life may of themselves play an important part in the etiology of this morbid assemblage of symptoms, but it is not the less true that it is in a measure to be imputed to overfeeding. By causing congestion of the liver this sets up inflammation of the biliary passages. It follows that the mucus secreted by the glands of these canals acquires an acid reaction and decomposes the biliary acids, which then lose their solvent power and allow pigment and cholesterin to be deposited in the form of small concretions, or biliary sand, the starting-point of calculi. In common with hepatic colic, nephritic colic is not very rare in children during the second infancy, or even during the period of nursing. Sometimes the new-born present uric-acid infarctions in the canals of Bellini, in the calices, and in the pelvis of the kidneys. The origin of this renal lithiasis before birth is rather obscure, but the diet of the mother and hereditary influence may be considered to play an important part. During lactation overfeeding may be a cause of disease. In the second period of infancy authors commonly recognize the influence of excessive feeding and of a diet containing too much animal food. Similar affections, as Bouley has shown, occur in young animals. As regards the skin, the correlation existing between various skin diseases and gastro-intestinal derangements in children is indisputable, and these gastro-intestinal troubles are very often due to overfeeding, which therefore should be considered as very commonly the primary cause of these different cutaneous affections. According to Brocq, symptomatic skin diseases may be the result of accidental poisoning by drugs, articles of food, or a morbid toxin; or of an organic disease acting in a reflex way; of progressive vitiation of the general condition; or of defective nutritive exchanges. In the cases of overfed nurslings, the first and second of these etiological factors do not generally play a part, unless the milk on which the children are maintained is of an extremely bad quality; but the same is not

true of an organic lesion acting in a reflex way, or of the imperfect nutritive exchanges which undermine the vitality of an organ and make it morbidly vulnerable. In the case of infants subjected to a mixed diet, or to a diet containing no milk, all four of these causes may come into play. As regards the genesis of certain skin diseases, such as urticaria, following the abuse of drink, and often observed in persons with dilated stomachs, a reflex action upon the cutaneous vaso motor nerves must be admitted, or in a weaned child, a direct action of ptomaïnes taken in excess into the system with articles of food. In other cases, on the contrary, and these are the commonest, where it is a matter, for instance, of impetiginous eczema, or seborrhoic eczema, or ecthyma, or different forms of acne, strophulus, etc., the pathogeny is probably different, in that case involving the direct elimination by the sweat-glands of volatile fatty acids which, in their passage through the skin, alter the anatomical elements of the integument. Among these various skin diseases there is one—eczema seborrhoicum of the hairy scalp and of the face—that is observed in large, fat children, who assimilate the great quantity of food which they take—that is to say, who bear overfeeding without gastro-intestinal troubles. One point it is very important to recognize—namely, that digestive derangement is not at all necessary to the production of skin diseases in an overfleshy or overfed child. In all these conditions it is a prime requisite of treatment to reduce the amount of food taken.

The Treatment of Fractures Involving Joints.—In the therapy of fractures involving the joints there is unanimity of opinion upon one point—that by a continuous immobilization a cure is very problematical. According to Dr. Klemm, if the patient is to regain good functional use of the joint there must be a proper balance in the treatment between rest and motion: rest of the broken bone; motion of the joint, muscles, tendons, and fascia. How these conditions are to be obtained is the subject of much controversy. In all joint fractures, as well as in most par-articular fractures, there occurs an extravasation of blood into the joint cavity and into the surrounding parts. The pathological changes which subsequently result are dependent upon the hæmatomata. To these changes belong: 1. Difficulty in placing and retaining the fragments in good apposition. 2. Changes in the joint cavity: *a*, thickening and toughening of the synovia; *b*, a growing together of the intra-articular parts of the joint surfaces by means of newly formed connective tissue (anchylosis). 3. An increase in density and cicatricial changes in the par-articular tissues. 4. Obliteration of the tendons in their sheaths. 5. Nutritive changes in the muscles. 6. Pressure and disintegration of the nerve-trunks, and, as a consequence, a possible neuritis with resulting disturbance of nutrition of bones and joint which result in deformities. 7. Hydrops of the joints as well as a firm œdema in the par-articular tissue. We can thus see how the presence of intra-articular and par-articular hæmatomata may affect the prognosis; and it is clear that these extravasations should be removed as soon as possible. What means have we at our command to accomplish this result, and how shall we use them? The therapeutic measures for the removal of such masses may be divided into two classes: the bloody and the non-bloody. To the first of these belong: 1. Puncture of the blood tumor and its removal, with or without subsequent irrigation. 2. Incision into the mass and its removal; with this may be classified also the suture of the bony fragments. Under the non-bloody modes of treatment are: 1. Compression. 2. Massage. The first method would appear to be of chief value in those cases only where there is such large extravasation of blood that gangrene of the distended soft parts is to be feared; just as incisions are made into infiltrated tissues, so that the relief of existing pressure will prevent subsequent occurrence of necrosis. The method of incision with subsequent suturing of bony fragments is to be reserved for cases where there is already an injury to the soft parts, or where the injury is so extensive that a reposition and coaptation of the fragments of bone is impossible without suturing. At any rate, it seems unjustifiable to suture the bone at the outset in a simple fracture, before it has been determined that any other mode of treatment will give bad results. Massage and compression are the factors which, when combined with active and passive motion, play the most important rôle in the treatment of joint fractures. Massage fulfils both indications for a rapid absorption and prevention of atrophy. Degeneration and new-growths are also restricted by massage. Compression acts more in a passive way. Massage increases the circulation in the affected region, new tissue formation is favored, and the veins and lymphatics are rendered more patent, so that the extravasated fluid is pressed by the manipulations directly into these and so carried away. Compression aids these results by increasing the *vis a tergo* in the time between the use of massage, and so serves to increase absorption. Hand in hand with these manipulations, active and passive motion should be used, which should vary in extent from time to time and thus, by changing the points of contact, prevent degenerative changes in these parts. As frequently happens in the use of a new method, some have gone to the other extreme, and recommended an entire absence of splints and immobilization, and entire reliance upon massage and motion. This is certainly wrong. The broken bone needs rest, and this indication must be met by the use of splints and bandages, and a proper position. Of course, cases vary greatly, and good judgment must be used to give each form of treatment its proper relative value.—*Annals of Surgery.*

Desternalization of the Ribs.—Dr. Jaboulay, surgeon to the Hôtel-Dieu of Lyons, writes on the subject of desternalization of the ribs and its employment in the treatment of large purulent accumulations in the pleura and in that of scoliosis. When, he says, in the dead body the costal cartilages are detached from the sternum, or when they are simply cut through at about their middle from the first to the seventh, the side of the chest-wall corresponding to the divided costal cartilages will be seen to become flattened, especially behind, and to become contracted transversely, the ribs tending to the median line and in front of the sternum. This change in the shape of the chest is still more evident when the corpse is placed in a sitting posture. If it is stretched out on the back, the weight of the upper limbs, through the medium of the clavicles, drags the first and second ribs away from the median line instead of allowing them to approach it, as all the other ribs do. The same change takes place on both sides. If bilateral desternalization is practised, or if the sternum is removed, the chest becomes narrowed transversely to an extent equal to the whole breadth of the sternum, or even a greater extent. It will be understood that by means of this double measure one may contract the thorax almost at will by adding transverse compression to the narrowing set up by this operative procedure. These effects may be made use of in the treatment of purulent pleurisy, when it is not cured by puncture and by the ordinary operation for empyema. Unilateral or bilateral desternalization or resection of the sternum seems preferable to the resection of a great number of ribs, as the latter procedure in severe and inveterate cases is not likely to prove successful. The author insists upon this point, that when a rib is removed the transverse sinking of the chest-wall affects only the level of that rib and a portion of the intercostal spaces above and below it, and diminishes at the same time the height of the side of the chest, so that, in order to completely efface one side of the chest, as is commonly necessary in cases of enormous effusion, it would be necessary to remove all the ribs. Desternalization, on the contrary, affects all the true ribs, and makes the corresponding half of the chest entirely mobile.—*New York Medical Journal.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 17, 1894.

THE NERVE-THEORY OF MENSTRUATION.

In a paper recently read by Christopher Martin, F.R.C.S., before the British Gynecological Society, the author elaborates a new view of menstruation, or rather of the relation of that function to the nervous system. He believes that there is a menstrual "centre" in the lumbar spine analogous to those for micturition, defecation, parturition, etc. This view finds in the author's mind a support from the general arrangement of the nerves of the pelvis. The uterus is supplied by the ovarian, and by the utero-vaginal plexus. He also admits the existence of the so-called splanchno-pelvic, which are described by Gaskell as arising in the lumbar part of the cord in the cells of the posterior vesicular column of Clark, and being also connected with the cells of the lateral horn of gray matter. They may be distinguished by the fineness of their fibres from other nerves. They run in the nerve-roots of the second and third sacral nerves, and pass from these directly into the hypogastric plexus, without entering the chain of lateral ganglia. From this plexus they are distributed to the generative organs, and also to the bladder and rectum. They are chiefly vaso-dilator in function, that is, they transmit impulses which bring about vascular engorgement in the viscera supplied. It is probable, therefore, that they are concerned in bringing about the determination of blood to the uterus and appendages, which is such a marked feature of the menstrual epoch.

In extension of this theory Martin finds the disturbances of the menopause due to a condition of instability and increased excitability of certain other cerebro-spinal centres brought about by the failure of the menstrual centre. He further adds that it is probable that the ovaries, like the liver and the thyroid gland, modify the blood circulating through them, and add to the blood some peculiar product of their own metabolism. It may be that some of the climacteric symptoms are due to the loss of this substance from the system.

Martin finds further confirmation in the case of a woman (already described in medical literature), twenty years old, whose body bifurcated below the waist, the spine dividing at the third lumbar vertebra. She had two pelves, each with its full complement of internal and external genitalia. Menstruation appeared at the usual age, was normal and simultaneous on both sides. If the menstrual centre was in the uterus or in any pelvic ganglia, menstruation would not have so occurred. As it is inconceivable that two independent menstrual centres, each in its own pelvis governing its own uterus would have kept synchronous beat, there must have been a higher centre in the body above the point of bifurcation governing both uteri, and bringing about the process of menstruation in each at exactly the same time.

A similar line of reasoning will show that ovulation cannot be the cause of menstruation, for it is most improbable that Graafian follicles would rupture in different ovaries, in different pelves, month after month at the same time.

Menstruation is defined by Martin as a katabolic process. A katabolic nerve stimulates the destructive metabolism which is always going on in the tissues. It frees energy, and such escape is followed by exhaustion. Now comes in the anabolic nerve to repair the damage and build up the tissue to its normal status. Between the menstrual period the uterus is governed by the anabolic fibres. It is engaged in constructive metabolism. If impregnation does not occur within a certain period, katabolism occurs and menstruation results. The endometrium cells rapidly degenerate, "the fabric of the half-formed decidua tumbles to pieces," the turgid capillaries burst and pour out the menstrual flow which sweeps away the useless tissue débris. If, however, impregnation occurs, the anabolic influence not only increases but continues until gestation is finished. Then katabolism anew gains the ascendency and parturition takes place.

Where the appendages are removed the arrest of menstruation may be explained by the withdrawal of a tonic nerve influence running in some way from the ovary reflexly through the menstrual centre to the uterus. More probable is it, however, that the operation severs the nerves governing the menstrual process. Against this view has been advanced the fact that in certain cases menstruation continues where both sets of appendages have been completely removed. In such a case the nerves have probably taken (one or both) an unusually deep course in the broad ligament, and so have been left behind.

The pseudo-menstrual discharge frequently seen after removal of the appendages is due, according to Martin, to the mechanical stimulation of the end of the divided menstrual nerve by the traumatism of the operation.

MEDICAL BULLETINS CONCERNING DISTINGUISHED INVALIDS.

THE author of the Code of Medical Ethics sends to the *British Medical Journal* the following memorandum and suggestion regarding the subject of medical bulletins. It ought to be read by all physicians.

"That much difference of opinion exists on the question may be taken for granted. Looking at it, however, from a medico-ethical point of view, I am strongly inclined to the opinion that undue importance (stimulated, it may be, by a feeling, more or less acute, of jealousy) has been attached to the passing notoriety gained—or rather assumed to be gained—by the affixing to medical bulletins of the signatures of the attendant practitioners, from which, nevertheless, I firmly and conscientiously believe that beyond the personal gratification possibly derived by a junior practitioner from the transient publicity accorded to his name, but little, if any, professional advantage is gained.

"If, indeed, as some allege, the practice merely pandered to the public appetite for sensational news, it could not, in my opinion, be too severely criticised and condemned. When, on the other hand, it arises from a purely honest public anxiety for authenticated information in the dangerous illness of, for instance, an illustrious or popular statesman, a distinguished prelate or esteemed dignitary, or some noble character beloved and respected by the nation, I not only fail to realize any valid objection thereto, but am forcibly impressed with the conviction that, in such and like cases, the natural public solicitude may be legitimately gratified without in any degree impairing professional morality; as a matter of fact, indeed, under the implied limitations the prescriptive custom of issuing signed bulletins has an evident meaning and the sanction of weighty precedents. Moreover (and the question may, I think, fairly be asked), if the signatures of the faculty in attendance be deemed relevant and essential in bulletins relating to royalty, why should the principle be regarded as irrelevant and objectionable in cases of special note, though of minor national importance? Be that as it may, it is, I apprehend, to the form rather than to the substance of bulletins that exception is generally taken—inasmuch as when the desired information is simply recorded in a newspaper paragraph, but without the customary signatures, no grave objection would appear to be raised. The conventional practice, withal, is one that it has hitherto been found impracticable or inexpedient to prohibit; and whenever the question of its abuse unhappily arises, it should be ethically determined according to the essential and collateral incidents of the particular case. At the same time the multiplicity of bulletins, the ill-judged flourish of titles and degrees, and the insertion of unnecessary details are always open to obvious objection and reproof. Need I add that personal modesty and good taste—two important factors which could not fail to exert a healthy restraining influence in the framing of bulletins—are natural gifts not always to be found in one and the same person, much less are they equally shared by all alike. Be that as it may, in view of the non-existence of any rule, written or traditional, by which the faculty should be governed in issuing bulletins (by some regarded, rightly, as a possible mode of covert medical advertising) in the illnesses of distinguished patients, I should hail with much satisfaction the authoritative utterance of the respective Royal Colleges—jointly or severally—on the subject, which would tend to allay contention, and thereby promote the true interests of the profession—an appeal which I would hope will sooner or later meet with an effective response in the form of a carefully defined rule. Meanwhile, in the hope of averting contentious criticism, and so far to promote professional harmony, I would suggest, as ethically essential—

"That in all cases of illness, except in the Royal Family, or of notable personages of national interest (in which professionally authenticated daily reports are rendered more or less imperative with the view to allay public anxiety), the medical attendant or attendants shall loyally withhold their signatures from bulletins; and, further, shall not allow their names to appear in any paragraph published in the newspapers relative to their patients; a contrary course, in so far as it may constitute a covert mode of unprofessional advertising, is opposed to the best traditions of the faculty and justly condemned by it, as are all oblique, indirectly inspired, and unauthorized communications to the lay press.

"Practitioners, moreover, will best consult their own honor and dignity, and true personal interests withal, by a conscientiously rigid but courteous refusal to be interviewed by reporters, or other non-related persons, with reference to the illness of patients; in regard to whom the desired information should emanate solely from, and its responsibility (clearly expressed) be accepted by the patient or his family.

"In a word, the principle enunciated in the following old Hippocratic adjuration should constitute the simple rule and guide of the Faculty of Medicine:

"'Quæcunque inter curandum videro audiverove, siquidem ea effari non expediat, silentio suppressurum.'"

A perusal of the foregoing will show that the author's views are wise and sound, and do not differ from those taught and generally practised in this country. We should take exception, however, to the necessity of publishing bulletins of the Royal Family. It would be justified no doubt in the case of the Queen and the heirs apparent, but we see no reason why all the little princelets, including grandchildren, uncles, aunts, and cousins, should receive bulletins. We should consider it very bad taste in American physicians to do this sort of thing.

THE WORKHOUSE AND ALMSHOUSE HOSPITALS.

We referred recently to the trouble between the Medical Board of the Almshouse and Workhouse and the Charity Commissioners. The outcome has been that Dr. Le Boutillier, who was most active in the agitation, has been compelled to resign. In a communication to the *New York Times* Dr. Le Boutillier makes a very fair statement of the case for the Medical Board.

After reciting the futile efforts of this Board to get the needed reforms, he says:

"So called 'economy' thus brought the daily cost of each inmate down below even the old rate of eight cents a day, while the number of inmates declined and the actual number of deaths rose. The efforts of the Medical Board to remedy the grave state of affairs above described extended to official and unofficial letters and visits to various Commissioners of Charities. But, relying on the 'luck' of the department and disregarding facts as to a rapidly rising death-rate and figures showing overcrowding that the Medical Board considered dangerous to health, they took no active steps, and the time passed for securing from the Board of Estimate and Apportionment the necessary increase of funds so to care for the sick and destitute of the city under their charge that they shall not suffer from bad or insufficient food or overcrowding in unsanitary dwellings.

"With the close of 1893 the number of applicants for relief largely increased, and the overcrowding of past seasons began again more intensely, but this time at the workhouse. With their old disregard of 'capacity,' or air space, the Commissioners sent men to the workhouse till they had less than four hundred cubic feet of air apiece, the amount required by the Sanitary Code for the poorest tenement-house in New York City being six hundred. As before at the almshouse, so this year at the

workhouse, there was the same old condition of dangerous overcrowding for the well and the same lack of adequate accommodations for the sick in the way of beds, fresh air, and proper food and nursing.

"What course can be taken by the comparatively few island visitors of the Medical Board, unheeded by the officials charged by law with the proper care of the institutions, than one to insure publicity of the actual facts? Of course, under our carefully devised system of elastic and evasive responsibility for municipal government, an appeal to the public may appear to the Commissioners to show an 'animus rather than a desire to correct abuses,' supposing the Commissioners to mean by 'animus' personal animosity."

After denying the charge of personal animosity, he continues:

"Lacking this personal animosity, the charges of official neglect have to be met by the old means of forcing the resignation of any members of the Medical Board who chance to be unpleasantly active or resist the Commissioners' desire for silence in regard to the actual facts of overcrowding, deficient food, and an appalling death rate, as shown by official documents in their possession."

We feel that while there was some indiscretion on the part of one of the Medical Board, their position as regards the needs of the hospitals must be correct; and it is not at all unlikely that the special attention which has been aroused in the matter by the recent agitation will result in good.

SARSAPARILLA.

There is, so far as drugs are concerned, a great deal in a name. This is particularly the case with regard to sarsaparilla. By long custom, through the influence of tradition and expensive modern advertising, sarsaparilla has become fixed in the public, and to some extent in the medical, mind as a "blood purifier." This fact lends potency to prescriptions, for the patient experiences a certain mental satisfaction in feeling that he is taking an accredited depurative, while the doctor experiences a sense of satisfaction in the belief that he has advised the use of a drug with such a respectable history.

There is, however, not a single tangible fact which shows that sarsaparilla has any medicinal properties at all.

Sarsaparilla root contains a very minute amount of an ethereal oil, and a principle which would be called active if it were not inert. This principle has been called paraglin, smilacin, and various other names. Its composition is said by Merck to be $C_{18}H_{30}O_6$. Some authorities have asserted that it possesses some power as a diaphoretic, but if so it is only slight, and secondary to the nausea produced by large doses.

No one has ever been able to show that the drug itself produces any tangible physiological effects, though Palotta, Böcker, and Schroff are the only authorities that have tested this point.

All systemic writers on therapeutics, including Rossbach and Nothnagel, Wood and Lauder Brunton, admit that the alleged therapeutical virtues of sarsaparilla depend on tradition rather than on any special observations or actual tests. Ringer does not even mention the drug.

Despite this, most writers succumb to the influence of tradition and admit the oft-repeated legend that it is an alterative, and in some inscrutable way—if given with other drugs—may be of use in scrofula, syphilis, chronic skin diseases, and perhaps rheumatism.

There are so many new drugs of demonstrated utility at the present day that it would be wise to drop all the useless ones; and we see no reason for retaining sarsaparilla in the Pharmacopœia simply because it may be administered pleasantly with iodide of potash. Unless, however, the medical profession says decidedly that radix sarsaparilla is of no use whatever, it is in some danger of becoming the ginseng of the American nation.

THE TAX ON INCOMES OF PROFESSIONAL MEN.

One of our correspondents has called attention to the fact that the proposed income-tax applies only to the excess over $4,000 and not to the total income. This fact does not, of course, invalidate in any way the point which was made by us, namely, that as the incomes of medical men increase, their expenses increase in such proportion that few physicians are able to save money or become capitalists, no matter how successful they may be.

We notice that our English brethren are starting a crusade against the income-tax which the Briton has to pay. A correspondent of the *British Medical Journal* shows that the real estate or landowner or bondholder who gets from his rents and interest an income of say $8,000, pays no more than the physician who earns the same amount. Yet the physician's income is entirely dependent upon the retention of his health and mental faculties, and, perhaps, from his freedom from rest or vacation. The property-holder may be ill, but his income continues, and he is justly taxed upon a real and permanent possession, but the medical man is taxed upon the results of his brain work, results which are, we are sorry to say, irregular and fugacious. Of course this applies also to the incomes of all professional men.

THE VIVISECTION OF CRIMINALS.

The medical profession has from time immemorial been enlisted on the side of humanity, and its best directed efforts have been toward mitigation of human suffering. That it may continue in these glorious lines of work is the wish and hope of its thousands of votaries. Our aspirations in these regards have, however, received a sudden and severe shock by the news that in Ohio an attempt is being made to so alter the law for the execution of criminals that the victims can be subjected to vivisection for what is claimed to be the benefit of science. The advocate of this repugnant, unreasonable, and we may say unscientific and really cruel procedure, is reported to have urged the claims of the bill on the following grounds:

"He thought it a good way for the condemned person to pay the debt he owed to society. He would have the condemned person placed under the influence of an anæsthetic, his stomach, heart, or brain exposed, and these organs studied in the living state.

"The subject should be kept alive until the questions pursued are solved, and finally executed by drugs. He did not think it would be necessary to inflict much pain in performing these vivisections."

We do not think that any physician can read the above without a feeling of repulsion and disgust. There is no

sentiment among medical men in favor of such a proposition. It is vulgar, sensational, and it is degrading to the profession. Medical science is based on humanity, and medical work illustrates every day the power of human sympathy and charity, but the deliberate mutilation and subsequent poisoning of human beings for any purpose whatever is too shocking to be seriously contemplated. Physicians are the very last to ask that their science be advanced by anything so brutal and demoralizing as human vivisection. We leave all this to the sportsmen and the warriors.

It is legitimate to have a decent ardor for the advancement of science, to study every means to such an end, to advocate every measure that may tend to the perfection of our knowledge of the relation of diseased to healthful processes, but we must in all such endeavors remember that we are gifted with reason and compassion, that even in the punishment of criminals we can stop short of torture, ever remembering that

> "Taught by that Power that pities me,
> I learn to pity them."

News of the Week.

The Four Years' Course at Columbia College (College of Physicians and Surgeons)—The entering class bids fair to be the largest in the history of the college, despite the lengthened course. Medical education in the leading institutions of this country is fully abreast of that in the Old World.

The West End Medical Society.—At the annual meeting of the West End Medical Society, held February 3, 1894, the following officers were elected for the ensuing year: F. Spencer Halsey, M.D., *President;* S. V. Ten Eyck, M.D., *Vice-president;* F. J. Blodgett, M.D., *Recording Secretary;* H. G. Meyers, M.D., *Treasurer;* H. S. Houghton, M.D., *Corresponding Secretary;* C. B. White, M.D., *Pathologist.*

Another Remarkable Newspaper Operation.—A man in Newark who has suffered from chronic hiccough has become the subject of a sensational experiment. The medical attendants, after publicly airing their theories regarding reflex irritation as the cause of the disease, sever the dental branch of the inferior maxillary nerve. But the hiccough does not stop. It is unfortunate that such cases are allowed such publicity. It stultifies the profession at the expense of advertising a so-called bold operator. The greatest wonder is how all these remarkable operations are so minutely detailed in the newspapers without the knowledge or connivance of the principals.

Dr. Lassar, who was Secretary-General of the Berlin International Congress, has been made Professor of Dermatology.

A Society for the Healthy Education of Youths has been organized in Berlin. It ought to include the maidens.

The New Antidote for Morphine.—It is reported that a man in Arkansas, who attempted suicide by taking three grains of morphine, was treated by the new antidote, permanganate of potash, and quickly recovered. Dr. Moor's article, in the present number, gives a coincidental interest in the subject.

The After-Care Association.—At the annual meeting of the "After-Care" Association for Poor Female Convalescents on leaving Asylums for the Insane, held on January 15th, it was estimated that there were about thirty thousand women of various callings and conditions of life in lunatic asylums in England and Wales. Of those a large number are discharged recovered in the course of the year; many very poor, and some friendless, but capable and anxious to earn their own living. The present association was formed to assist such by obtaining for them when needful an interval of change of scene and air, by placing them in a convalescent home, and by boarding them out in the country when thought desirable, under proper care and supervision, by giving them grants of money and clothing, and by assisting them to obtain suitable employment.

A Large Fee and its Use.—A story recalling a characteristic trait of the late Sir Andrew Clark is told by a correspondent of the *Daily News.* The correspondent writes in reference to the statement in the *Strand Magazine* that "as regards fees Sir Andrew Clark always took what was offered." This statement, says the correspondent, conveys a false impression. Sir Andrew always took what was offered when it was less than his ordinary fee, but not when it was more. Then an illustrative case is mentioned with regard to the physician's visit to Cannes some years since. On returning to London the patient he went to see sent him a check for £6,000, which Sir Andrew returned, saying he could not accept it, as it was excessive, his fee being £750, not an excessive sum, considering it took him away from his practice for a week. The patient paid the fee and returned the first check, asking Sir Andrew to employ it for the benefit of the suffering sick poor, a wish which, it is needless to say, was faithfully carried out.

An Excellent Reason.—The *Pacific Medical Record,* published at Portland, Ore., has transformed itself into *The Medical Sentinel,* the reason given for the change of name being that "there is but one MEDICAL RECORD in the United States, and that is the one published in New York City."

Chicago's Death-rate.—The report of Health Commissioner Reynolds for the year just ended mentions the low mortality-rate of Chicago as compared with other cities, and then gives an opinion touching the cause of such condition as "due without doubt to our fortunate location between the broad prairie on one side and Lake Michigan on the other, giving free play to the breezes that dilute and sweep away the impurities of the air." The total number of deaths for the year 1893 was 27,059, which is a rate of 16.91 per 1,000, "the lowest rate, with one exception, in fifty years."

Another Post-Graduate School.—Rumor has it that there is already organized a new post-graduate school in this city. It is in connection with the German West Side Dispensary, a heretofore modest institution on West Thirty-eighth Street.

The Congress of German Dermatologists will hold its fourth annual meeting in Breslau on May 14th.

National Guard Surgeons Organize.—The Association of the Medical Officers of the National Guard and Naval Militia of the State of New York was formed last week, in the armory of the Tenth Battalion, Albany. Organiza-

tion was effected by choosing the following officers: *President*, General Joseph D. Bryant; *Vice-Presidents*, First Brigade, Major D. M. Stimson, Seventh Regiment; Second Brigade, Major W. E. Spencer, Twenty-third Regiment; Third Brigade, Major Herman Bendell, Brigade Surgeon; Fourth Brigade, Major Albert H. Briggs, Sixty-fifth Regiment, Buffalo. *Secretary*, Lieutenant Daniel S. Burr, Assistant Surgeon, Separate Company, Binghamton. *Treasurer*, Colonel N. H. Henry, assistant to the Surgeon General. The constitution provides that the Executive Committee shall consist of the officers of the Association and five members to be appointed by the President. They will be appointed, one from each brigade and the naval militia. The following committees will soon be announced, and the surgeons of each brigade and the naval militia will have a representation in each: On Organization of Hospital Corps, Equipment of same, Drill and Regulations of same, Construction of same, Sanitation and Technique of Field Surgery.

Partisanship appears to be exceedingly acrimonious in Germany. The Leipzig Society of Physicians has just expelled two republican members, lest their membership prejudice the pecuniary interests of the government employees who are members of the society.

The International Sanitary Conference was held at Paris on February 7th. Among the French representatives were Professors Brouardel, Proust, and M. Monod; Germany was represented by MM. de Schoen and Mordtmann; Austria by Count Kuefsten and Dr. Hagel, and the United States by Drs. Stephen Smith, E. D. Shakespeare, and P. H. Barthacha. England alone, of European countries, was not represented, a fact not much to her credit. England has always been too much afraid of her tradesmen to engage herself in any entangling sanitary pledges.

A Brooklyn Doctor gets a column notice in the daily press for his extraordinary heroism in supplying blood to an exsanguinated patient. This is not a rare occurrence in medical experience, and one must conclude that in Brooklyn heroes are cheap.

No Scarlet Fever at Harvard.—It is denied that there is any scarlet fever at Harvard College. It is only a crimson fever.

Rise in the Price of Life.—The damages given to heirs for a death through negligence of railways, etc., has heretofore never been over $5,000. An Arkansas jury, however, has just given a verdict for $20,000 against the Little Rock & Memphis Railroad.

Dr. Walter D. Green has been appointed by Governor Pattison, physician to the port of Philadelphia.

Dr. Emily Winifred Dickson, of Dublin, has been elected the first female fellow of the Royal College of Surgeons, Ireland.

Insanity Statistics.—The Annual Report of the State Board of Charities, submitted to the Legislature February 1st, shows a total increase in the number of insane in the institutions of the State, from October 1, 1880, to October 1, 1893, of 8,842. The increase in population from 1880 to 1892 was twenty-eight per cent., while the increase of the insane in the institutions was eighty-three per cent. A part of this increase, it is stated, may be accounted for by the greatly increased accommodations, by means of which many insane had been taken from their homes to institutions. Besides, the better care of the chronic insane has doubtless considerably prolonged their lives. Still, the Board believes that the increase is not wholly accounted for by these causes. The number of patients in the various State hospitals for the insane on October 1, 1892, was 7,484; the number of admissions during the year ending September 30, 1893, was 2,586, and the total number under care during the year, 10,070, as against 9,435 the preceding year.

Gifts to Hospitals.—The will of Mr. Andrew L. Kidson, of New Haven, Conn., bequeaths $5,000 to the General Hospital Society of New Haven. The Sheltering Arms Hospital at Charleston, W. Va., has received a gift of $17,000 from the widow of Ex-Governor Olden, of New Jersey.

A Verdict for the Physician.—Dr. William Marvin Bemus, of Jamestown, N. Y., who was recently the defendant in a suit for alleged malpractice, has won his case, Judge Green deciding in his favor, that there was no cause of action. The circumstances of the case are as follows: On March 19, 1892, the plaintiff, a woman, forty-one or forty-two years of age, slipped and fell on a stone walk, in the city of Jamestown, producing a badly comminuted Colles's fracture, with dislocation of ulna, and displacement of extensor carpi ulnaris. A Levis's splint was used, and removed in a little over three weeks, and passive motion commenced, which was practised three times at intervals of three days. Upon calling the fourth time the doctor found his patient had left the city and gone to Hydetown, Pa., to try the virtues of a patent liniment, where she remained about three weeks. There was no evidence that the limb was manipulated during the time she was absent, and the fact is, that it was not. It should have been stated before that the plaintiff claimed that her shoulder was dislocated at the time of the accident to the wrist, and that the surgeon failed to discover it. Upon her return from Hydetown, she went to another physician, who, she claims, and so testified, reduced the dislocation, and advised her to have the wrist broken over. This physician, upon being put upon the stand, testified that the shoulder was not dislocated, and that he broke down some adhesions, the result of bruises. He also contradicted the plaintiff as to having the wrist broken over. A number of physicians were sworn for the defence, all of whom examined the arm and pronounced the result as better than could have been expected under the circumstances. Judge Green said among other things, there has been a perfect exculpation, by the evidence, from all negligence or want of skill on the part of the defendant, and a perfect vindication of the manner in which he treated this plaintiff and of the result which he obtained; and while professional men were held to the strictest degree of duty toward their clients and their patients, when they have done that they certainly ought to have the fullest and most complete vindication, and it seemed to him there had been given that to this defendant by the evidence upon this trial. The evidence had shown that he did all that a skilful and experienced surgeon could do under the like circumstances, and that the result was as good as it was possible for men to obtain, and he therefore directed the jury to find a verdict in favor of this defendant of no cause of action.

Society Reports.

PATHOLOGICAL SOCIETY (LONDON).

Aneurism of the Aorta.—Dr. Voelcker showed a specimen of aneurism of the aortic valve, which occurred in a child eighteen months old who died from capillary bronchitis following measles. The heart contained a pale adherent clot on the right side. The left ventricle was not much enlarged. On the posterior cusp of the aortic valve there was a mass the size and shape of a small cherry-stone. This was moulded by the semi-lunar cusps and projected down toward the ventricle, dragging the aortic cusp with it. The valve was not perforated. There was no sign of endocarditis or of infarcts. Dr. Voelcker did not believe that the pouching of the cusp was the result of endocarditis or a hemorrhage into the valve, but was of the opinion that a patch of fatty degeneration had altered the nutrition of the overlying endothelium, that fibrin had been deposited from the blood, moulded into form by the other cusps, and the patch yielding to the pressure above the cusps, and being dragged down by the mass, had formed an aneurismal pouching of the valve. Such polypi on the cusps of the aortic valve in children he believed to be rare.

Inflamed Vermiform Appendix.—Dr. Smith presented a specimen of diseased vermiform appendix removed from a man who during life presented no symptoms referable to this appendage. The patient had had an attack of nephritis which had nearly recovered, and then, after a few months, relapsed. The patient died apparently from acute uræmia. At the autopsy, the kidneys were found slightly enlarged, mottled, and with adherent capsules. The stomach and intestine down to the colon showed patches of intensely red congestion, but no ulceration. The appendix was pale, about the size of the forefinger and curved on itself as the result of adhesions. In its mesentery there was a small black hemorrhagic swelling. Dr. Smith considered the case a typical example of recurrent appendicitis and thought the specimen might throw light on the possible condition underlying many cases of appendicitis in which the patients recovered under medical treatment only.

LONDON CLINICAL SOCIETY.

Acute Phthisis.—Dr. Fenwick read a paper on two cases of acute phthisis following destruction of the mucous membrane of the stomach by corrosive fluids. A man, thirty-four years old, had severe gastritis after swallowing oxalic acid, which lasted upward of six weeks, this was followed by symptoms of subacute gastritis. Under lavage, considerable improvement manifested itself, so that he gained eighteen pounds in weight. Four months after the gastritis the patient contracted a cold which was attended with cough, fever, sweating, rapid emaciation, and death within six weeks from acute phthisis. The necropsy showed a condition of caseous tuberculosis invading both lungs from apex to base, with a small cavity in the right upper lobe.

The second patient had swallowed some nitric acid and had following this a prolonged attack of subacute gastritis accompanied with marked dilatation of the stomach. Seven months after the accident the patient began to suffer from cough, night-sweats, and fever. These symptoms increased in severity. The gastric symptoms returned, evidence of progressive consolidation of the lungs became manifest, and death followed in a few weeks. The autopsy showed the lungs to be the seat of acute tuberculous infection from apex to base. The mucous membrane of the stomach was completely destroyed.

Dr. Fenwick said it was of interest to remark that in each instance a corrosive fluid had destroyed the digestive activity of the stomach. It would therefore seem that the sudden impairment of nutrition had so diminished the resistance of the tissues as to render them particularly vulnerable to tuberculous infection.

Membranous Inflammation of the Throat During Scarlet Fever.—Drs. Goodhall and Washbourn spoke of the results of their observations of cases of membranous inflammation of the throat during scarlet fever. In cases where the membrane is tough and thick, accompanied by a well-developed rash, the diagnosis must be made between, 1, severe scarlatina anginosa with membrane; 2, diphtheria with rash; and 3, coexisting scarlatina and diphtheria. An absolute diagnosis can only be made by a careful bacteriological examination. They believe that a membranous inflammation of the throat occurring during the acute stage of scarlet fever is generally not true diphtheria, but that a similar condition occurring during convalescence is true diphtheria. These conclusions are in accord with the results of bacteriological examination.

FRENCH SOCIETY OF DERMATOLOGY AND SYPHILOGRAPHY.

Buccal Ulcers.—Dr. Wickam, in a paper presented to this Society, described special buccal ulcers occurring during the course of locomotor ataxia. These ulcerations, which have not yet been described, present such characteristics that they may be considered diagnostic of tabes. The principal diagnostic points laid down are as follows: 1. The seat of the ulceration is at the dento alveolar junction. The ulceration entirely, or at least in part, is at the margin of the alveolus. 2. The atonic aspect. 3. Indolence and anæsthesia. 4. Exploration with a probe frequently demonstrates that the surface-opening leads down to denuded bone. 5. Chronic evolution. 6. Loss of teeth; this frequently occurs without pain. 7. Deformity of the maxillary bone. This deformity arises as the result of the alveolar ulceration, necrosis of the bone, and elimination of the sequestrum, etc. He emphasizes that this inflammatory process occurs without pain, as does the falling of the teeth. These characteristics differentiate this variety of ulceration from that associated with tuberculosis, syphilis, phosphorus necrosis and intense mercurial stomatitis. The nature of these tabic lesions is uncertain. Dr. Wickam is not certain whether these lesions are purely trophic or whether they are not an affection *sui generis*, which finds a favorable soil for its development in tabetic patients. Dr. Fournier proposed that these ulcers be referred to as buccal perforating ulcers.

BERLIN MEDICAL SOCIETY.

Demonstration of a Case of Syphilis of the Spinal Cord Followed by Recovery.—Dr. Feilchenfeld presented a patient who had suffered for upward of six months with severe symptoms of spinal cord syphilis and who, under the influence of antisyphilitic treatment, went on to recovery. The patient had been infected with syphilis two years previously, and had had well-marked secondary, for which he was treated by inunctions of mercury. During the course of this treatment the patient became anæmic and emaciated. While making a journey he became chilled and soon after this he suffered from extreme pains in the back and from girdle sensation. The legs became tired easily, and he had difficulty in controlling the urine and bowels. In a few days he developed markedly ataxic gait, but the knee reflexes were still preserved. Sensibility of the lower extremities was almost completely lost, and he could not distinguish between warm and cold. Two weeks later it was quite impossible for him to lift his legs from the bed, so that he had an entire paraplegia. A diagnosis of syphilitic meningo-myelitis was made, and the patient was placed in a hospital and subjected to a rigorous antisyphilitic treatment, particularly by means of inunctions and vapor baths. After fourteen days his recovery went forward rapidly, so that at the time of reporting his case all the symptoms, except a slight diminution of sensibility in the left leg and some diminished tonicity of the sphincter ani, had disappeared.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-eighth Annual Meeting, held at Albany, February 6, 7, and 8, 1894.

HERMAN BENDELL, M.D., PRESIDENT, IN THE CHAIR.

SECOND DAY, WEDNESDAY, FEBRUARY 7TH—MORNING SESSION.

Discussion on Abdominal Surgery.—DR. ALBERT VANDER VEER had arranged a discussion on this subject, but several of the papers were read by title.

Disputed Points in Pelvic Surgery.—DR. JOSEPH PRICE, of Philadelphia, read a paper with this title. He thought much was said and printed which was far from scientific or in accord with the teachings of advanced surgery. An evil of the profession was the too prevalent medical journal. These were often established to act as mediums for nostrums or anything which would pay for space; "as the French say, 'all cats are black in the dark,' so all names are on paper." Often statements were given as facts which were pure fiction. Pus in the pelvis or tubes was rarely dangerous *per se*, said some, and on top of this it had been gravely stated that even if the tube were broken down with puriform degeneration, it might be preserved as an aid to the production of pregnancy. The authors of such nonsense failed to consider that such tubes were by universal consensus of opinion of the best observers made responsible for ectopic pregnancy. Among rash procedures, was thrusting a needle through the abdominal parietes and allowing the patient to walk home. Loss of physiological organization carries with it loss of physiological function.

Dr. Price thought this was a generally recognized law, yet there were some who took the remarkable stand that it did not apply to the tubes and ovaries.

Influences Affecting the Results of Abdominal Operations.—DR. J. F. W. ROSS, of Toronto, Canada, read the paper. Similar cases, operated upon under antiseptic precautions, did not always give equally good results as the surgeon had reason to expect. Why? The author, in analyzing possible influences in cases occurring in his practice, had come to the conclusion that one factor was the air. This had seemed to act injuriously under conditions where he had reason to believe it contained impurities; weather conditions, however, had also an influence. Where impurities of the air had been credited with affecting the peritoneum injuriously, Dr. Ross excluded possible infection through the hands or instruments. Might not the peritoneum respond to a poison in the air which could not be detected by sight, or perhaps by smell. Some condition inherent in the patient might influence the result of the operation, such as scrofula or tuberculosis, malaria, etc. The cases most likely to die after abdominal section were those in which a septic condition had existed some time before the operation. A difference in the virulence of the contained pus of tumors or tubes must be assumed to account for the difference in fatality of some cases apparently similar in other respects.

Hemorrhage after Abdominal Section.—DR. A. H. BUCKMASTER reported a case of fatal hemorrhage the fourth day after removal of diseased appendage, the cause being found at autopsy to be slipping of a portion of peritoneum out of its constricting band. The pedicle had been tied in halves and in whole. He had supposed himself very unlucky in losing the case from this cause, for similar cases in literature were very rare, yet on conversing with his acquaintances he had heard of fifty accidents of this nature. They were not reported in the journals, one reason for which it could be assumed was danger of suit for malpractice. The author thought some cases of death without clear cause had been of this nature and overlooked because no autopsy or only an incomplete one was made. There was no certain means of knowing that hemorrhage was occurring in the closed peritoneal cavity until it was too late to save life. The drainage tube was not a guide, and as to distention, this of course, occurred too late. The necessity for prevention by care during the operation became evident.

Cysts of the Epigastrium.—DR. DUDLEY P. ALLEN, of Cleveland, O., in this paper gave the histories of two cases of cyst of the epigastrium, a term which he used in preference to that of cyst of the pancreas, since their exact origin was not evident, although they were attached to the pancreas among other organs.

In the first case a tumor had appeared, giving fluctuation over the entire front of the abdomen, but being most prominent at the left of the umbilicus. Diagnosis of cyst of the pancreas was made, although the possibility of cyst of the kidney and gall-bladder had been borne in mind. The aspirating needle brought away dark brown fluid, coming apparently from a hæmatoma. The abdomen was opened six hours later, the cyst was found attached to the walls, the pancreas, colon, etc. A glass tube was inserted and left for drainage. Nine months afterward the patient vomited much dark colored fluid; a physician was summoned, who removed a living child from the uterus by cæsarian section, the woman died and an autopsy was made twenty-one days after burial. It revealed the fact that the cyst was attached to the pancreas, but the structure of this was not changed, and the conclusion was reached that the cyst was the result of hemorrhage which had undergone changes due to long retention. The second case was that of a boy of nineteen years who had observed swelling of the abdomen since receiving a blow over the episgastrium ten years before. The stomach was below the cyst in this case, while in others it had been between the stomach and transverse colon. He opened the cyst, and packed with gauze. The fluid contained much cholesterin and emulsified fat, no tripsin, nothing to show that it came from the pancreas.

The author referred to the investigations of Mr. Lloyd regarding the possibility of occurrence of cyst of the omental bursa, the outlines and extent of which had been shown by injections, and expressed his own belief that there were cases in which fluid collected in the omental bursa as a direct result of injury to the pancreas or liver, the fluid being either blood or mixed with the secretions of the injured organ. The second case seemed to be one of this nature. In rabbits it had been shown that the fluid poured out into the bursa could be taken up very rapidly by the lymphatics of the diaphragm, and it was thought the same might occur in man.

In the discussion, DR. HOWARD KELLY and DR. A. G. GERSTER expressed the opinion that the title of Dr. Price's paper, Disputed Points in the Treatment of Pelvic Surgery, was not justified by its contents; that the points brought up were no longer disputed. They also expressed disapproval of what they took to be general assertions impugning the motives, and reflecting upon the intelligence of the profession. Referring to drainage, they employed this only occasionally, and Dr. Kelly said it was his custom to have the pus examined immediately when he opened the abdomen, and if it contained pyogenic streptococci and staphylococci he was much more likely to drain than if it did not contain these germs, which pointed to greater virulence of the fluid. Referring to Dr. Ross's paper, they thought that where the air had been credited for an unfavorable wound the real source of the trouble was faulty antisepsis.

DR. CHARLES P. NOBLE upheld drainage practised as frequently as some did in Philadelphia, on the basis that the more favorable statistics justified it, and, referring to the same subject, DR. PRICE supposed it might be very scientific to be guided in the use of the drainage tube by microscopical examination of the pus for germs, but intimated that it would be much safer and more practical to put the drain in in doubtful cases, since in any event it could hardly do harm and might save life.

Case of Acromegaly.—DR. FLOYD S. CREGO, of Buffalo, presented a woman who showed the condition called acromegaly, of which about thirty undisputed cases had been reported in literature. It was characterized by enlargement of the bones, and somewhat of the fleshy

parts; in a number of cases there had also been exophthalmic goitre, and the patient shown had had this affection about six years prior to the enlargement of the bones, but since the commencement of acromegaly the projection of the eyes had diminished. She was now thirty-one years of age, and showed enlargement of the facial bones—head, hands, feet. In London they had considered removal of the pituitary gland, which was enlarged in many cases and had been supposed to bear an etiological relation to the acromegaly, but the author thought this procedure impractical. It might be wise, however, to try the treatment of myxœdema.

Dr. T. R. Pooley had examined many patients with exophthalmic goitre, but had never seen it combined with acromegaly, and therefore concluded that the latter affection was very rare.

Dr. Sherman, of Ogdensburg, said the late Senator Irwin in the last years of his life presented the appearance of this patient, and was believed to have had acromegaly, but he had at no time shown signs of Graves's disease.

Dr. Frederick Remington, of Buffalo, sent photographs of a case of acromegaly which were presented by Dr. Potter.

Dr. Angell said that in many cases of acromegaly there was deterioration of the mental faculties, but the woman exhibited was an exception. Dr. Crego said closer inquiry had shown that probably over fifty per cent. of cases did not have deterioration of the mental faculties.

Three Cholecystotomies for Gall-Stones, with Recovery.—Dr. W. W. Seymour, of Troy, related in a paper the histories of three cases of cholecystotomy for gall-stone, all of the patients recovering. He entertained very pronounced views as to the relative merits of certain methods. Excision of the gall-bladder, in his opinion, had no field except in malignant disease or gangrene. Again, the operation of cholecystotomy in two stages had no advantages which the simple operation in one stage did not possess many times over. In another case like his third one he would make cholecystenterostomy. With all respect to internal medicine, he must say that the time had come when gall-stones should be regarded as a surgical affection which required prompt intervention when the attacks became frequent or severe. Nothing would dissolve the stones when once formed. The paper was discussed briefly by Dr. Mynter and the author.

Palpation of the Vermiform Appendix.—Dr. George M. Edebohls, of New York, read the paper, describing the manner in which one could palpate even the healthy appendix as well as the enlarged one, and the value of the information derived therefrom. The practicality of the procedure had been tested by him in many cases the past year, mostly on females, but also on three males. The correctness of his conclusions had been demonstrated on opening the abdomen where for some reason an operative procedure was indicated. The success of the method had also been demonstrated in one case by his colleague, Dr. George F. Shrady. After examining other organs, one proceeded to palpate the appendix. Only one hand, applied externally, was required; no assistance was afforded by a finger in the vagina, and very little and only occasionally by one in the rectum. Standing at the patient's right, apply two, three, or four fingers over the abdomen and notice successively the character of the structures which came beneath them as they passed from the umbilicus to the spine of the ilium, sufficient pressure being used to feel the posterior wall of the pelvis. The appendix, when normal, felt more or less flattened, ribbon-shaped, or more or less firm and rounded when thickened by inflammation, more or less sensitive when diseased. It was usually found almost immediately outside the iliac vessels. Its variable location, and its common deep situation behind the cæcum were not against palpating it. The heretofore assumed distention of the caput coli by fæcal matter scarcely ever existed.

The Inch-and-a-Half Incision and Week-and-a-Half Confinement in Appendicitis.—Dr. Robert T. Morris, in a paper written under this title, stated that we had recently learned four principal things relative to appendicitis, and he was now asking the members of the profession to accept a fifth point. We had learned that, 1, appendicitis was of very common occurrence, 2, that many forms of abdominal inflammation were symptomatic of appendicitis, 3, from statistics, that late operation did not give much encouragement, 4, that early operation was with trifling mortality, but there was danger of ventral hernia if a long incision were made. The fifth point was that a long incision was not needed when cases were operated upon at the outset of the inflammation.

The author advised one inch and a half abdominal incision, the uniting of the structures with fine catgut, and the burying of the stump of the appendix with Lembert sutures. The abdominal scar disappeared so that it could not be seen at the end of a few months. His death rate was nothing in all cases without pus. He did not approve of carbonate of sodium for reversing peristalsis of the bowel, but used chloride of sodium for that purpose in all his operations.

Dr. Morris said that opposition to the plan of removing the infected appendix as soon as it was discovered must fade away when physicians learned that appendicitis was an infectious exudative inflammation which did not disappear on disappearance of the symptoms.

He also stated that he had removed two or three appendices which were apparently normal, but the patient's symptoms had stopped and cultures of bacteria and microscopic sections from these proved that they had been dangerously infected, and the mucosa and adenoid tissue were undergoing destruction by the colon bacillus.

Dr. Morris said that when his inch-and a-half incision was employed, the patients left the hospital at the end of a week and a half; when a two-inch incision was made they were not ready to leave until fourteen days after the operation; and when a two-and a-half to four-inch incision was made eighteen days were necessary for repair. Consequently he had adopted the inch-and-a half incision and week-and a-half confinement plan, which left no hernia and an evanescent scar.

By operating immediately in acute cases, he did not mean the following day, but the following hour.

Pseudo-Diverticulum of the Duodenum.—Dr. Louis S. Pilcher reviewed the literature of duodenal diverticula, stating no record of true or pseudo diverticula of any size of that gut appeared, other than the record of a case in the West back in the thirties. He then related the history of a young man, seventeen years of age, who, in a state of marasmus and with irritative septic symptoms, and an indistinct tumor in the middle of the abdomen, was received into the Methodist Episcopal Hospital of Brooklyn in November last. Here an abdominal section was made, which displayed a heart-sized and shaped tumor, with its base hidden above under the transverse colon. This burst under examination, giving issue to pus and bile; upon enlarging the opening partially digested food was also found within it. The cavity was cleansed, and drainage provided for. Forthwith a free flow of bile began to issue from the drains, and milk swallowed by the mouth at once thereafter appeared on the dressings. A fatal peritonitis ended the case on the third day. The autopsy disclosed that two-thirds of the wall of the transverse portion of the duodenum were wanting, and the descending portion of the duodenum opened freely into a large cavity, whose walls were made up largely of infiltrated connective tissue, the whole constituting the tumor which had been formerly appreciated. From the left upper angle of this cavity the jejunum issued, being connected to the duodenum by a relatively narrow strip of mucous membrane. The biliary papilla was discoverable just within the duodenal orifice. This cavity had formed an interruption or diverticulum from the alimentary canal, into which all food was received and held for a time while in transit.

The specimen was submitted, together with plates showing the condition at the time of operation, and the minute anatomy of the specimen.

Appendicitis: The Connection Between its Symptomology and the Gross Anatomy of the Appendix.—Dr. Joseph D. Bryant read this paper. The gross anatomy of the appendix and its variable location had been described by him elsewhere, and was based on studies at one hundred and forty-four autopsies. In only three of this number was the appendix extra peritoneal. Speaking of pain at any fixed point, he said that the varying directions of the appendix, its difference in length in different cases, together with tenderness along the sigmoid, from which it arose, all conspired to make the establishment of a fixed point of pain impossible and reliance on it misleading. Tension of the right rectus abdominis was an important symptom, being a conservative process, but the tension, for the same reason, was apt to affect the left side as well and also deeper muscles, the psoas and iliacus, which caused flexion of the thigh. The bladder and rectum often became tender, especially if the appendix extended into the pelvis; and other parts were apt also to become sensitive. The conclusions from the paper were: That the location, extent, and direction of the appendix had an important bearing on the history of the appendicitis, and that well-recognized variations in length, direction, and location of the appendix made the establishment of a definitely stated diagnosis upon the seat of pain unwise and misleading.

Intestinal Perforation in Strangulated Hernia.—Dr. W. B. De Garmo read the paper (see future issue).

The several papers just read were discussed together, and in some remarks upon appendicitis, Dr. Herman Mynter, of Buffalo, alluded to the difference in the mortality rate according to the nature of the cases. He had not lost a patient until a year ago, then he had a number of fatal ones, and the reason was that previously they had not been of the kind in which there was perforation with general septic peritonitis. He would like to know how the surgeons in New York city, where they apparently lost no patients, would account for their wonderful success.

Dr Durand related a successful case of acute perforation with gangrene, in which he gave credit for the recovery to washing out with a solution of peroxide of hydrogen.

Drs. Willy Meyer and R. T. Morris, of New York, were willing to grant Dr. Mynter's premises and would account for their greater success in New York by the fact that physicians there had learned to call a surgeon early. Dr. Edebohls referred to two successful cases of perforative appendicitis, and the discussion was continued by Dr. Vander Veer and Dr. Bryant, who admitted the fatal tendency of perforating appendicitis accompanied by general septic peritonitis, the class of cases which, some of the speakers might have forgotten, had alone been referred to by Dr. Mynter when he spoke of their extreme fatality.

Recent Methods of Gastrostomy for Stricture of the Œsophagus.—Dr. Willy Meyer, of New York, read the paper, which was illustrated by drawings. Among the methods which he described were those of Witzel, Sabanejew Frank, Fenger, Hahn, and Von Hacker. He gave the preference to Witzel's. Operators used to see doctors temporizing with cases of œsophageal stricture. Why? Because they saw patients die quicker with than without operation. The fluid would ooze out of or alongside the tube, cause painful eczema and starvation, because it was impossible to keep the wound closely adjusted around the tube. This objection to operative interference or gastrostomy held no longer, for there were a number of methods at the surgeon's disposal which would enable him to prevent regurgitation through gastric fistulæ. Cases which the author had operated upon were mentioned, and the opinion was expressed that Witzel's method was an excellent one and the best.

Some Cases of Head Injuries.—Dr. Herman Mynter, of Buffalo, in this paper referred to twenty-seven operations for injuries of all kinds to the head which had come under his charge within some months. Four of the twenty-seven were severe fractures of the base, all proving fatal. Three of the entire number deserved special mention. In one the diagnosis was made of subdural hemorrhage in the facial area, there having been motor-symptoms referable to the face and arm, and aphasia. Three ounces of blood clot were found beneath the dura at the site of the trephining. The patient recovered and the aphasia and paralysis disappeared. In the second case the patient, five or six weeks after the injury from a fall, began to get drowsy, show stupor, and some fever. Abscess was diagnosticated, and on trephining was found near the motor area. In the third case the patient had been injured on the left frontal region, was well apparently six years, then began to show mental stupor and drowsiness, with epilepsy unattended by convulsions, and passed into status epilepticus. There was improvement after trephining, then relapse, but so far apparent cure after a second operation. Attention was called to the fact that only sterilized water should be used on the brain, for it was extremely sensitive to antiseptics, 1 to 10,000 bichloride acting injuriously.

The Action of Scopolamine on the Eye.—Dr. Thomas R. Pooley, of New York, reviewed in this paper the roseate experience with this new mydriatic described by two continental writers, and which had led him to give it a trial beginning with last August. It belonged to the group of atropine, was contained in hyoscyamine without being identical with this, and the preparation which he had used was Merck's. Its action was found to be about five times as strong as that of atropine, and was much shorter by twenty-four to forty-eight hours, which made it much better in examining the eyes for errors of refraction than sulphate of atropine, although the influence of hom atropine passed off in about equally short a time, and the latter, contrary to the statement of writers abroad, less frequently caused toxic symptoms. Dr. Pooley had had two cases of pretty severe toxic symptoms from scopolamine.

A New and Almost Bloodless Operation for Prolapse of the Rectum.—Dr. Edward Clark, of Buffalo, in a paper with this title, reviewed some of the difficulties of other operations for prolapse of the rectum, especially that of controlling hemorrhage, and then described the method which he had carried out in a single case with the loss of little more than a drachm of blood. The gut being prolapsed as if the finger of a glove were partially inverted, it followed that the portion in view was double. He placed an elastic ligature around the prolapsed portion up at the anus, which controlled the circulation, then cut off the extreme end, then separated the internal and external portions of the protruding gut, tied a ligature around the internal portion, which prevented passage of fæces and hemorrhage, and thus gave opportunity to remove the elastic ligature above. The external portion having been separated up to the anus, was cut off, and the stump was carefully stitched to the inner portion, after which the latter below the stitches was cut off. The end then immediately drew into the anus. In his case there had not only been no suppuration but no rise of temperature, or scarcely any.

Tuberculosis and Health Boards.—Dr. Mallory offered a resolution, which was adopted, earnestly urging local boards of health to place tuberculosis on the list of infectious diseases, and approving the efforts of the State board to control this disease.

Third Day, Thursday, February 8th—Morning Session.

Report of Committee on the President's Address.—Dr. Eugene Beach read the report. It recommended a reapportionment of delegates in several counties to correspond with the number of assemblymen as required by the constitution. Also that presidents of county societies

be made ex-officio members of the State Society for their term of office, but without privilege of voting or becoming permanent members. Donations of private medical libraries to the State Medical Library were encouraged, and larger appropriations were urged by the Legislature. They did not recommend at present holding meetings elsewhere than at the Capitol, as provided by law. Dr. Pilcher, however, sent in a minority report on this point, recommending that alternate meetings, in accord with the President's address, be held at other places than Albany. On motion, the minority report was rejected and the majority report was adopted.

No Prize Essays.—Dr. Townsend, of Albany, read thereport of the committee, that, as usual, no essay had been received in competition, a fact which was much regretted.

The report of the Committee on Publication was read by Dr. F. C. Curtis, and was adopted.

Delegates from Voluntary Societies, Colleges, and Asylums.—Dr. Burr, of Binghamton, gave notice of an amendment to the by-laws, allowing one delegate from incorporated voluntary medical societies, incorporated medical colleges whose by-laws were in accord with those of the State Society, and each State hospital for the insane, and the New York Academy of Medicine five delegates.

To Incorporate Certain County Medical Societies.—Dr. Beach called attention to the fact that in counties created since 1814 the county medical societies had not been legally incorporated, and he moved that the Committee on Legislation be directed to seek appropriate legislation. The motion was adopted.

Fixed Fees for Attending Coroners' Inquests.—Dr. Maddren said he had offered a resolution two years ago, which was adopted by the Society, looking to legislation fixing the fees of physicians attending coroners' inquests, taking the remuneration out of the hands of Boards of Supervisors, who always cut down the amount, through false economy. As there was to be a hearing on the bill before the Legislature that afternoon, he requested that a committee be appointed to appear in favor of it. His motion was adopted.

Proposed Separation of Business and Scientific Proceedings.—Dr. Albert Vander Veer moved that the Committee on By-laws be requested to consider the question of separating the meetings devoted to business and those devoted to scientific matter, and to report at the next meeting. He thought there should be an earlier report from the Nominating Committee and that the scientific proceedings should not be entrenched upon by the business proceedings, and *vice versa*. Dr. A. F. Currier spoke in the same strain, and suggested there might be a business meeting Monday, the day before the usual time of meeting. Dr. Vander Veer's motion was adopted.

Quarantine Committee Continued.—Dr. A. W. Suiter read the report of the committee which had been appointed to seek national quarantine legislation, which had since been enacted, and he suggested the committee be continued or another be appointed to co-operate with the new Committee on Quarantine of the New York Academy of Medicine to seek the creation of a National Board of Health. The report was adopted and the committee was continued.

Uræmic Hemiplegia.—Dr. R. W. Wilcox read the paper. The existence of this condition had been denied by such authorities as Addison and Bright, Lécorché, Sée, Loséque. On the other hand, cases had been reported since 1880 by Charpentier, Pätsch, Jäckel, Raymond, Chantemesse, Tenneson, Bernard, Lancereaux, Level, Chaufford, Dreyfus, Brisac, Florand and Canniot, Lloyd and Dercum. Dr. Wilcox also reported his own case, in which the patient recovered, but in which the diagnosis was undoubted.

The clinical histories of the reported cases presented great uniformity of symptoms and signs. Careful questioning was important, and the existence of prodromal symptoms should be established clearly, for upon the presence of these symptoms—they were rarely absent—was placed great dependence in diagnosis.

Symptoms: 1. Vertigo, often slight. 2. Gastric symptoms, nausea not relieved by stomach medication, beginning apparently without cause. 3. Cardiac. If hypertrophy of the left ventricle, it should be remembered that this predisposed as well to cerebral hemorrhage. 4. Localized œdema of the face, eyelids, and patches in the lungs.

Signs.—1. The urine was likely to be albuminous before the hemiplegia appeared. If it was only discovered afterward, this symptom lost much of its significance, for it was often found in hemiplegia from hemorrhage or softening. 2. Persistent low specific gravity of urine was important; casts, if found, would do much to aid in forming an opinion. 3. If only hyaline casts were present, the general import of the urinary finding was increased, for in contracted kidney these might be the only casts present. 4. If atheromatous changes were apparent, it might be suspected that the cerebral arteries presented the same changes. 5. If albuminuric retinitis was present, as was rarely found, there was great probability that uræmia was the cause of the hemiplegia.

Conclusions.—1. Uræmic hemiplegia was a distinct form. 2. The peculiarities were its mobility, variability, and complete recovery. 3. The diagnosis rested upon the antecedent history, condition of the urine and temperature curves. 4. The dominating factor in treatment was the uræmia.

Dr. E. D. Fisher referred to two cases, said the diagnosis was very difficult, an important point being uræmic symptoms before the hemiplegia.

Dr. W. W. Seymour thought too much attention was given albumin and not enough to quantitative examination of urea.

The Barber-shop as a Source of Contagion.—Dr. Geo. Thomas Jackson read the paper. (See future issue.)

Dr. F. C. Curtis, of Albany, thought all had probably seen cases now and then where the barber had spread infectious diseases epidermal in character, but seldom others, especially syphilis.

Dr. Van Ranken said that in a Troy institution ringworm of the scalp persisted among the inmates, three hundred children, until they discarded the use of a hair-clipping machine, and Dr. Jackson said there had been a similar experience in an institution with which he was connected.

Glycosuria.—Dr. W. B. Vanderpoel, of New York, in this paper considered mainly the treatment of glycosuria cursorily, observing that, as with albuminuria, so with glycosuria there exists a functional and also a morbid form, the latter called the diabetic, depending on pathological changes in the liver, pancreas, or nervous centres. Two sets of causes are recognized: 1. Predisposing, which includes heredity, race, climate, sex, obesity, environment, and age. 2. Exciting, viz., traumatic, disorders of peripheral nerves or centres, functional or structural, profound mental shock or strain, exposure to cold or moisture, prolonged errors in diet, certain physiological states, certain diseases, drugs, or poisons.

Treatment.—1, Prophylactic; 2, hygienic; 3, dietetic; and 4, medicinal.

1. *Prophylactic treatment* embraces avoidance of all exciting causes, and especially those having inherited tendency or already showing the functional form.

2. *Hygienic treatment* includes regulation of diet, exercise, bathing, dress, etc.

3. In *dietetic treatment* the object sought is to diminish the glucose in the blood, and, if possible, restore the bodily power to assimilate sugar. At first carbohydrates alone augment the glycosuria; later, nitrogenous foods, and even the proteids of the body go to swell the flood. Hence, early, by limiting the carbohydrates good results follow, while later, a mixed diet offers less strain to the renal structures, and in personal cases by its substitution for rigid nitrogenous diet, impending diabetic coma has been averted. Fats are of service early to sup-

ply to the body elements ordinarily derived from carbohydrates and protect the albumin of both food and tissues from being seized to maintain the combustion necessary to the animal functions. Later, the fats may be attacked themselves and increase the glucose supply, but even yet are of some protective value. Ordinary bread, in one-half or one-fourth the customary amount, yields better results than the deceptive diabetic flours in the market used *ad libitum*, as they all contain starch.

4. In *medicinal treatment* opium ranks pre-eminent in its power to lessen glucose formation and also the polyuria. Codeia (gr. ¼ to ½), t.i.d., and later every two to four hours. Bromides control nervous symptoms, but have no direct effect on the glucose formation; sodium and lithium salts are the best borne.

Arsenic used in Giliford's or Clemens's solution, or in combination with lithium carbonate (gr. iij.), and sodium arsenite (gr. $\frac{1}{48}$) in a syphon of Vichy water, and drank in one or two days. Coal-tar derivatives, antipyrin, phenacetin, sulfonal, are all of value, phenacetin most so.

Ergot and ergotine counteract vaso-motor paresis in hepatic circulation. Good results are thus attained.

Alkalies and alkaline waters increase the blood alkalinity, and so enhance the oxidizing powers of the body. Combined with sedatives, as codeia, phenacetin, etc., a maximum effect is attained. The purgative alkaline waters are most effective where sugar formation is excessive; the non-purgative where sugar assimilation is defective. Carlsbad and Vichy are at the head of each class. Jambul is considered directly inhibitory to the glucose production in the intestine, and also acts through the medullary centre. The bowels are loosened, which, if not excessive, is of benefit. Results have varied, possibly due to capricious action, uncertain preparations, or pathological type of the disease.

Pancreatic preparations are of marked benefit in the wasting form of the disease. Pilocarpin in this same class, oxygen inhalations, hydrogen peroxide per orem, etc., are all of benefit. Strychnine, phosphorus, iodoform, transfusion of blood, electricity, benzosal, nitro-glycerine, etc., are among the drugs mentioned.

Personal method is a fairly rigid diet gradually inaugurated, the general condition of the patient being more closely observed than the actual sugar percentage in the urine. Codeia alone, or, alternately with phenacetin, and also the combination of sodium arsenite and lithium carbonate in Vichy water. In hepatic cases Carlsbad Sprudel salts in hot water before breakfast secures bilious stools, and aids our other general measures. For thirst, phosphoric acid lemonade.

The Treatment of Hernia.—Dr. Dallas, of New York, sent a paper supplementary to one which he had read last year on the treatment of hernia. He advocated greater personal attention to these cases on the part of physicians and the employment of suitable instruments, claiming that in so doing results could be secured both surprising and gratifying—the cure of the cases under puberty and of the majority of recent cases in adults.

There were also a number of other papers read by title.

Election of Officers.—The Nominating Committee, being unable to make their report unanimous on the name for president, presented the names of Drs. Geo. Henry Fox, of New York, and Henry Flood, of Elmira, five of the committee having voted for Fox and three for Flood. The Society then balloted for president and Dr. Fox was elected; 59 votes having been cast, 40 for Fox, 19 for Flood.

The remainder of the report was adopted as follows: *Vice-president*, Frank Low, of Pulaski; *Secretary*, F. C. Curtis; *Treasurer*, C. H. Porter; *Committee on Arrangements*, W. J. Nellis, of Albany, Josiah Hasbrouck, of Port Ewen, R. W. Wilcox, of New York; *Committee on By-laws*, H. D. Wey, of Elmira, A. R. Simmons, of Utica, F. C. Curtis, of Albany; *Committee on Hygiene*, Charles E. Bruce, of New York, H. R. Hopkins, of Buffalo, A. N. Bell, of Brooklyn, D. S. Burr, of Binghamton, Lewis Balch, of Albany, E. H. Loughran, of Kingston, O. W. Peck, of Oneonta; *Committee on Legislation*, D. B. St. John Roosa and Daniel Lewis, of New York, and D. V. O'Leary, of Albany; *Committee on Ethics*, John S. Warren. Charles Jewett, Eugene Beach; *Committee on Prize Essays*, Franklin Townsend, Jr., A. W. Suiter, C. Stover; *Committee on Publication*, F. C. Curtis, W. W. Potter F. D. Bailey, C. H. Porter; *For Honorary Membership*, George M. Sternberg, U. S. A., O. E. Herrick, of Grand Rapids, J. S. Stone, of Washington, A. T. Cabot, of Boston, J. H. Packard, of Philadelphia; *Eligible for Honorary Membership*, G. H. Rohe, of Maryland. A number of delegates to various medical societies.

A vote of thanks was extended the President.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 22, 1894.

Seneca D. Powell, M.D., President, in the Chair.

To Change the Coroner System.—The Comitia Minora having approved the resolutions passed recently by the Academy of Medicine, recommending a change in the coroner system, on motion the resolutions were endorsed by the County Society.

Resolutions in Accord with the President's Address.—The recommendations contained in the president's inaugural address led the Comitia Minora to recommend the following resolutions for adoption:

The Abuse of Medical Charities.—*Resolved*, That this Society adopt a resolution condemnatory of the practice in vogue at certain hospitals and dispensaries of giving gratuitous medical and surgical service to patients in a position to pay. Adopted.

A Suggestion to the Board of Health.—*Resolved*, That it is the sense of this Society that if the Board of Health is to preserve its usefulness in the community in the highest degree, it should extend to the family physician the same consideration which one member of the profession owes to another. This resolution was laid on the table for future action.

Expert Medical Testimony.—It is recommended that the bar association be requested to appoint a committee of five to meet a like committee from the County Medical Society for the purpose of considering the question of expert medical testimony, and for effecting such legislation as may seem desirable. Adopted.

Legislation Relating to the Practice of Medicine.—It is recommended that all legislation suggested by members of the County Society, relating to the practice of medicine, either as between physicians or between the physician and the community, should be first submitted to this Society and receive its approval before it is transmitted to the State Society or proposed for enactment as a law, and that all such propositions should be referred to the Comitia Minora for careful consideration before any official action be taken. It is further recommended that the by-laws be amended at the next annual meeting in accordance with the above recommendation.

Some doubt was expressed as to whether this resolution would not interfere with the rights of members as individual citizens, and to first bring proposed legislation to the attention of the Academy of Medicine (and presumably other societies with which they might be connected). The resolution was adopted.

The Opium Disease in Children.—Dr. Louis Fischer read the paper. In it he described a number of cases of the opium habit, or, as he preferred to call it, the opium disease, in children, which had been brought on by the administration of this drug in some form for intestinal or other trouble. (See page 197.)

The Unreliable Nurse.—Dr. F. M. Crandall also believed the opium habit in children was far more common than was generally known. He had seen many cases, even in very early infancy, especially in babies under the care of a nurse. The child might be well the

first two weeks or twenty days except perhaps for constipation. Then the monthly nurse leaving it would become very restless and "upset." In one instance the mother, who had had the same nurse at the birth of several of her children, said she dreaded the time when the nurse was to go away because she had such a time with the baby. Dr. Crandall learned that this nurse was in the habit of giving the baby paregoric while it was under her care.

The Prescribing Druggist Reprimanded.—Dr. H. D. Chapin thought it was not only common for druggists to prescribe and sell paregoric to mothers for the ills of their children, but they also wrote on the label how many drops constituted a dose. This was bad practice, for the mother, noticing the quieting effect of the drug, limited its use only by the number of drops said to be a dose. He believed the tendency of physicians was coming to be against the use of opium in the diseases of children. There was less danger at their hands than at the hands of the ignorant mother and nurse.

Another speaker gave warning of the danger in cough drops, and expressed the opinion that more children died of the opium taken in this and other forms than of bronchitis.

Puerperal Sepsis, Its Modern Prophylaxis and Treatment.—Dr. R. W. Murray read a paper on this subject. In spite of the recent advances of midwifery, especially of aseptic midwifery, he was convinced that a large number of physicians had not kept pace with this department of medical art. In the term puerperal sepsis he included those mild forms which led to subinvolution of the uterus and a "poor getting up" after confinement.

Labor was a natural process, physiological, and, if properly managed, should not be followed by fever or septic manifestations. If it was, it indicated that there had been some fault in the technique. In the vast majority of the cases the septic matter was conveyed to the parturient woman through the vagina by means of the examining finger, hands, or instruments.

Puerperal sepsis involved a number of tissues, according to the point or extent of the inoculation, but as all cases had the same cause, sepsis, he would on this occasion only stop to inquire how the septic matter entered and what should be the treatment. He would not deny that now and then the poison entered the system through other channels than the genital tract. The veins, lymphatics, and continuous mucous tracts were the usual channels. Among the phenomena attributed to puerperal sepsis were phlegmasia alba dolens, and thrombosis in the lungs and elsewhere.

Prophylaxis.—Prophylaxis was obtained by preventing the entrance of germs, and this was secured by antisepsis before confinement, antisepsis after confinement, shutting off the genital tract after labor, and securing contraction of the uterus. He used the term antisepsis because it was only through antisepsis that asepsis could be secured. The prophylactic treatment which they advocated and employed at the Maternity and in private practice required little time, was not burdensome nor expensive. The antiseptics which they had employed were corrosive sublimate, carbolic acid, and creolin, the latter being preferred by Dr. Murray because of its freedom from certain objections which pertained to the others. Before confinement the patient's clothes were changed, the external genitals were cleansed, she occupied a bed in a sunny, well-ventilated room, new sheets, a rubber cloth, two yards wide, covered with a slip-sheet. The bowels were moved by enemata, and in this connection the reader expressed the opinion that a good many cases of infection were due to the fact that the bowels had not been moved, fæces were forced down during labor and infected the hands of the accoucheur, and through them the genital passages of the woman. A napkin was placed a little under the sacrum. The nurse was instructed not to make a vaginal examination before the arrival of the physician. The latter washed his hands, cleaned his nails, used a nail brush, immersed the hands in bichloride solution, 1 to 2,000, touched nothing until the vaginal examination had been made, if it was intended to make one. Creolin could be used to lubricate the hands. The antiseptic pad was ready to apply immediately after extraction of the child, and was left on until the placenta came away, when another was applied. Expression was used in placental extraction, the hands were not introduced. If, however, any membranes remained, they should be brought away at once. If the hand had been introduced into the uterus, or if the liquor amnii were foul, or other unusual occurrence had taken place, the intrauterine douche should be employed, the uterus being held meanwhile in a state of contraction with the hand on the abdomen. With this exception, no douche was given during the puerperium. The external parts were bathed with creolin, and a pad was applied over the vulva, the patient was cleansed, clean sheets were placed beneath her, a dose of fluid extract of ergot was given after the labor, especially if there were any tendency to uterine relaxation. In hospital practice the urine was usually drawn with the catheter every eight hours.

In evidence of the superiority of the antiseptic method in midwifery, Dr. Murray quoted the statistics at the Maternity Hospital for periods prior to the antiseptic method and subsequent thereto. The former showed a mortality from septic causes of 4.17 per cent., the first antiseptic period only about a quarter of one per cent., and the last, during which there had been 957 confinements, no deaths from sepsis. In the 957 cases there had been 124 operations; deaths from all causes, 6. This excellent showing had been obtained in the face of the fact that the house staff and nurses were changed about every six weeks.

Inspection should always precede vaginal or intrauterine douche following labor, lest an infected clot or diphtheritic patch be carried up into the uterus. He believed puerperal diphtheria was more common than had been recognized. The source of any fetor should be determined. If from the uterus, it was apt to be from the corners where shreds of placenta were liable to be retained. The uterus being cleansed thoroughly, it was packed with iodoform gauze. If acute general septic peritonitis had already developed, laparotomy would be useless; it was different if the peritonitis were local. A case of rapid fatal septicæmia, death in twenty-four hours, was due to a nurse examining the patient before the physician arrived, the nurse having previously attended a case of diphtheria.

Recommends Laparotomy in Puerperal Septic Peritonitis.—Dr. Egbert H. Grandin thought an aseptic confinement should be followed by a perfectly afebrile state. As soon, therefore, as there was rise of the temperature and acceleration of the pulse, the heart and lungs being excluded as a cause, the physician should seek at once to locate the origin of the trouble. According to his observation the majority of cases of puerperal sepsis originated in the uterine cavity. He was opposed to what seemed to be the routine practice of simply giving a uterine douche or douches in such cases. The proper procedure was to examine the interior of the uterus with the finger before giving the douche, in order to be assured whether the source of sepsis was within that organ. If it was, then the more radical the treatment the better. The douche would not eradicate sepsis beginning and emanating from the uterus. It was necessary to make thorough dilatation, curettement, and efficient drainage.

A second point which he wished to make was that laparotomy should be performed for septic puerperal peritonitis whether it was local or supposed to be general, for, while it would in all probability prove fatal in spite of operation if it were general, we could not be positive in our diagnosis and might find but a local collection of pus on opening the abdomen, where we had expected general distribution. Acting on this principle, he had saved two lives the past three years which would have been lost had no operation been performed.

Dr. H. J. Garrigues said it was just ten years ago that he had read his first paper on the prevention of puerperal infection. Those who listened to it could have been divided into two classes, viz., those who believed puerperal disease hardly existed, and those who admitted its frequency but believed that the better results obtained by Dr. Garrigues's method would be found, as on other occasions, due to some other factor than the method itself. Many took a humorous view of the measures then advocated. Now, however, it had come to be generally admitted that the proper treatment and prophylaxis consisted in antiseptic midwifery. While this had come to be generally adopted in hospitals, we could not say as much for private practice. It was common for physicians to say that the patient could get along without all these precautions. Statistics, however, told a different story. How often did we hear of young women in the walks of society dying in their first child-birth. This meant infection, and infection could be prevented. The doctor should not make a vaginal examination without taking the same precautions that he would if he were going to perform a laparotomy. He should not enter the uterus at all before labor; all that was necessary was to feel the dilating os. He had been surprised to hear that it was the custom in the hospital to draw the urine with the catheter every eight hours after labor. Better let the woman urinate naturally if she could. He agreed with Dr. Grandin regarding cleansing the uterus in sepsis, and in opening the abdomen in septic peritonitis, both general and local, for that supposed to be general might be only local and amenable to treatment by laparotomy.

Dr. Rosenburg did not believe that puerperal sepsis would be eliminated until midwifery was placed altogether in the hands of physicians or educated midwives. An important lesson was taught by the fact that puerperal sepsis was scarcely known in certain localities where a vaginal examination was never made. One should use no antiseptic which would mask fetid lochia.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, December 28, 1893.

H. J. Boldt, M.D., Chairman.

Case of Absent Menses.—Dr. H. W. Mitchell gave a further account of the case of non-menstruation which he had first reported in February, 1892. The subject was an unmarried Irish girl, now aged twenty-six, who came to this country in 1888. There had never been any evidence of normal or vicarious menstruation. The only occurrence of further interest in the case was the fact that, about a year ago, she bled profusely after having a molar pulled by a dentist, but Dr. Mitchell did not regard this as connected in any way with absent menstruation. There had been no other indication of the hemorrhagic diathesis.

Ovarian Ligature Sloughed into Bladder.—Dr. Locke presented a silk ligature which had caused the formation of vesical calculi in a patient on whom an operation had been performed for sloughing ovarian tumor some months previously. After the operation for removal of the tumor, bladder irritation continued, she passed several calculi, and finally the ligature, which evidently had sloughed through the walls of the bladder.

The Chairman remarked that the case supported the position which he had long taken, that silk ligatures should not be used on the pedicle of abdominal tumors. Dr. Outerbridge, he said, had asserted that it was not unusual for them to find their way into the bladder.

Report of Cases of Accouchement Forcé.—Dr. S. Marx read the first paper of the evening, bearing this title (see page 202).

Objections Answered.—Dr. Egbert H. Grandin having been called upon to open the discussion, said he could wish someone else had first spoken, in order that he could, since he was known to be an advocate of accouchement forcé, answer objections which might be raised. The cases cited in the paper showed that the operation was an eminently safe one to the woman and a life-saving one for the child. They were quite in accord with his own experience. Therefore, notwithstanding the objections which had emanated recently from a distinguished source, he was still practising accouchement forcé when the necessity arose, and he expected to continue to practise it until a better method of saving mother and child should be offered.

The objections could be reduced to one, namely, danger of rupturing the uterus. So might version rupture the uterus, yet we were not going to reject version as an obstetric procedure on that account. The same remark applied to the forceps. Between himself and Dr. Marx fourteen or more cases of accouchement forcé could be cited, in which all the mothers and all but two of the children were saved, the latter being non viable; yet by any other method the probabilities were that all the children would have been lost. While it was possible to rupture the uterus, yet there was no necessity for such an accident, for absolutely no brute force was employed in dilatation of the cervix and lower uterine segment with the fingers. The cervix might rupture, but, as the author had said, there was nothing simpler than to repair a lacerated cervix immediately after labor, if the patient were placed upon her back. In the Sims position the procedure was much more difficult. The conditions in which he had resorted to accouchement forcé were placenta prævia and eclampsia, or impending eclampsia. The mortality to mother and child had been *nil*, whereas by methods which he had formerly employed in similar cases the mortality had been about fifty per cent. Obstetrics should in every respect rest on a scientific basis. The time had gone by when the pregnant woman should be allowed to die. If a woman engaged a doctor in time, he should, before her confinement, know her pelvis as well as he knew her face; he ought to recognize placenta prævia, pelvic deformity, and impending eclampsia, and should do the elective operation if an operation were called for at all.

On Neutral Ground.—Dr. Malcolm McLean said he looked upon the operation more favorably than he had ever done before, as it had been made clearer to him in the paper and during the discussion. At the same time he must say that certain statements were not in accord with his own experience. He had understood Dr. Marx to say that in placenta prævia the cervix was boggy. He had not so found it. The preparatory procedure of introducing gauze, which sometimes also effected delivery, was not regarded by him so favorably as hydrostatic dilatation by the improved Barnes bags. He would fear laceration of the cervix, and that the tear might extend even into the vagina. The danger of rupture of the uterus should not be underestimated. The suggestion by Dr. Grandin that version might also cause rupture, led him to remark that, according to his observation, it was trials with the forceps before version was performed which had caused rupture. No man should, under any circumstance, tear the uterus by internal version. If accouchement forcé were to be adopted too readily by the general practitioner we might yet expect to hear of ruptures of the uterus.

Dr. Edgar said his views of accouchement forcé were nearly in accord with those of the author and the first speaker. The experience of the past eighteen months, however, had convinced him that it was a serious operation, especially if performed rapidly, and therefore, when haste was demanded he preferred to combine with it Diihrssen's incisions, as he had done in one case which he related. In another case he combined accouchement forcé with symphyseotomy. Hydrostatic dilatation would have required too long a time.

Dr. R. A. Murray said that accouchement forcé meant rapid dilatation of the cervix, and also more or

less rapid extraction of the child. Whenever there was sufficient time the cervix should not be cut. It could always be dilated without it. If the cervix were anyways rigid, one man alone could not dilate it sufficiently with his fingers, but would have to be relieved by an assistant or by Barnes's bags. There was great danger of sepsis, which was enhanced by calling in assistance. Rapid delivery was also attended by danger of shock.

Dr. Marx closed. Rupture of the uterus was possible if brute force were used, but this was unnecessary. He objected to Barnes's bags because they could not always be obtained; or, if kept, they were likely to be rotten when required. Dr. Murray having referred to the danger of shock, he said that no operator would interfere while the patient was in collapse.

The Radical Cure of Umbilical Hernia.—Dr. George M. Edebohls discussed this subject, making use of illustrations on the board and presenting a patient. Herniæ which occurred in the median line of the abdomen were divided according to their cause into four varieties: Those due to fat, cœliotomy, pregnancy and tumors, and umbilical. He proposed to consider only umbilical herniæ. First, however, he pointed out certain differences between this form and the form which followed operations. The latter were more easily cured, for the reason that the separation of the walls was elliptical and their edges less retracted and attenuated. In umbilical hernia the edge of the opening was composed of thin white fibrous tissue.

In children a bandage or truss might answer, but in adults it was not to be used. It was difficult to fit, and should the hernia come out while it was being worn, injury would follow and there would be greater danger of its becoming irreducible. Every woman with an irreducible hernia was entitled to an operation.

As long as the hernia was permitted to remain it was exposed to injury, to incarceration, to the skin becoming extremely thin and inflamed, to phlegmonous inflammation through repeated attempts at reduction.

Dr. Edebohls then mentioned some reasons why operative procedures had failed, and went on to give the methods of operating which he had tried. The opening being a round one it was necessary to render it elliptical, so that if its diameter had been two inches its length would, after trimming, be as much as six inches. He had tried the flap-splitting method, splitting the thin walls back half an inch anteriorly and posteriorly, so that when they were brought together they presented a broad surface of union; but the trouble was that when the sutures were tightened the very broad walls were narrowed almost to a line. What was wanted was a means of union which would leave the flaps broad when united, and this was what he had been enabled to accomplish by the suture which he had described in his operations for perineorrhaphy. During four years' use in perineorrhaphy it had always secured primary union, and a second operation had never been called for. While it had not given equal success in umbilical hernia, yet it had proven very satisfactory. He first brought the flaps together with catgut and kept the line of union broad by inserting buried silkworm gut sutures, about three to the inch, and these remained after the catgut had become absorbed.

Hysterical Manifestations Due to Alcohol.—Dr. Henry C. Coe read the paper. The etiology of hysteria or hysterical manifestations was not always clear. Yet it could be detected by the observant physician in many cases where it was commonly quite overlooked, and the treatment, in consequence, was entirely misdirected. That tippling was not uncommon among fashionable women was well known, but visible effects of it were seldom shown except in unusual vivacity. It was only after unwonted indulgence that the old hands displayed symptoms which might be mistaken for hysteria. It happened, now and then, however, that young women of nervous type, and unaccustomed to alcohol, were for some reason led to take, for them, an excessive quantity and developed hysterical symptoms for the first time. Several cases had come under his observation, the first related being that of a young woman of high degree of intelligence, who had shown habitual self control, had never manifested hysterical symptoms, yet one morning astonished her family by manifesting much excitement, laughing, crying, throwing off her clothes, and behaving in an extraordinary manner. He learned that she had been out the evening before and had partaken of a moderate amount of intoxicating drink. The second case was similar, a young miss partook of two or three glasses of wine at a dinner, and that evening developed hysterical symptoms, tearing off her gown, and showing considerable excitement. There had been no previous attack and none since. Two instances were also given of hysterical excitement developed in fashionable women who were accustomed to drink, but on this occasion had some hours previously taken more than their accustomed amount. One case was that of a woman who had developed the tippling habit from having been given alcohol by her physician for the relief of pain of menstruation.

Every case of hysteria to which one was called should lead him to inquire as to the patient's drinking habits. It was important to remember, too, that a small amount of alcohol was sufficient to upset the nervous system of a nervous woman who was not accustomed to stimulants. The physician was in a position to exert an influence in the right direction with regard to the tippling habit and the dangers attending it. The best remedy for the hysterical attack in such cases was to secure sleep and cause the excretory organs to act. Dover's powder would quiet the nervous system and stomach, make the patient sleep, and bring on perspiration, so that after again awaking she would be found in her right mind. The physician who prescribed whiskey or brandy for a slight ill was scarcely less culpable than he who gave opium for the same reason.

Dr. R. A. Murray would give an emetic first of tepid water, if that would succeed.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MEMORIAL OF SIR ANDREW CLARK AT THE COLLEGE OF PHYSICIANS OR THE LONDON HOSPITAL — MEDICO CHIRURGICAL SOCIETY—ALBUMINURIC ULCERATION OF THE BOWELS—INTESTINAL OBSTRUCTION CAUSED BY HYDATID CYSTS—CLINICAL SOCIETY—HYDATID CYST OPENED THROUGH THE CHEST-WALL—MEDICAL SOCIETY OF LONDON—CYSTOSCOPIC EXAMINATION FOR FOREIGN BODIES—FRACTURED PATELLA—HORNY GROWTH ON THE PENIS—LORD COLERIDGE VICTIMIZED BY ANTIVIVISECTORS.

London, January 20, 1894.

That a memorial to Sir Andrew Clark would be projected was certain from the moment of his death. The only question about it was as to the form the memorial should take. Naturally the College of Physicians would like it to be in connection with their corporation, and a portrait or statue would be a fitting ornament to their building. Such a memorial would suit the profession perhaps, but it is hardly likely to commend itself to the public, and even medical men who are not connected with the corporation may think that a portrait or statue might very well be provided by the College itself. The governors of the London Hospital have taken time by the forelook, and held a public meeting at which their President—the Duke of Cambridge—took the chair. A resolution was passed in favor of a memorial in connection with that hospital—the field of Sir Andrew's life-work. It was suggested that a new wing, to be named after the lamented physician would provide much needed isolation wards. A committee was formed and a subscription list opened with a donation of £100 from Mr. Gladstone. It is possible, therefore, the governors of the London Hospital may further enlarge that which is already the largest hospital in the kingdom.

At the last meeting of the Royal Medical and Chirurgical Society, on the 9th inst., Dr Dickinson read a paper on "Albuminuric Ulceration of the Bowels," in continuation of cases he has previously published. In an experience of forty years he has met with twenty-two examples in which ulceration of the bowel was coincident with, and presumably pathologically connected with, renal disease. The ulcers were not confined to any part of the bowel, though they were most frequent in the lower part of the ileum, nor were they especially associated with any of the glandular structures. The most marked character of the ulcers was their association with hemorrhage. Two cases were adduced in which the stomach was ulcerated as well as the bowel, in one the ulceration being associated, as in the bowel, with extravasation of blood. In all the 22 cases the kidneys were diseased; in 14 they were granular; in 2, large white. In 19 of the cases hypertrophy of the heart was noted; in 9, there was retinal hemorrhage or exudation. Thus the albuminuric ulcer presented itself in company with other members of the cardio-vascular series to which it apparently belonged. The lesion mostly presented itself late in the course of the renal disease, and often brought about the fatal issue by means of peritonitis and perforation. The symptoms commonly present were griping, abdominal tenderness, diarrhœa, and vomiting. In a minority of cases no symptoms were to be observed.

Dr. White said the fact that ulceration of the bowel was associated with Bright's disease used to be taught by Sir William Gull and by Dr. Fagge. He had himself been interested in the subject from another point of view, for he had investigated it from the intestine as the starting point. Of twelve patients who suffered from ulcerative colitis, four were found to have granular contracted kidney, while a fifth had suffered from gout. Of the twelve cases, five of them had also ulceration of the small intestine, and of these five two had granular kidney and one gout. Perforation of these ulcers was common, and peritonitis was twice as common as perforation. When fatal, death was usually due to diarrhœa, exhaustion, or peritonitis. He therefore concluded that the albuminuric form of ulceration of the intestine was one form of ulcerative colitis. He had seen in all his cases evidence of colitis extending for some distance round the ulcers, and he therefore regarded the hemorrhage rather as an indication of the severity of the ulceration than as a cause of it. When extensive hemorrhage occurred in other regions extensive ulceration did not follow—as, for instance, in purpura—and the epistaxis of chronic Bright's disease was not usually accompanied by ulceration. In a recent specimen which had been sent him from Trinidad of dochmium duodenale there were multiple hemorrhages caused by the bites of the worm, but this had led to no ulceration. Dr. Mitchell Bruce said that he had met with two cases of very profuse hemorrhage from the bowel occurring in chronic Bright's disease. In neither case had he been able to prove the presence of ulceration, which, he thought, must be rare. Dr. Herringham referred to a specimen in St. Bartholomew's Hospital Museum of ulcers of the stomach, of the size of the end of the little finger, the base of each formed of a clot of blood. The specimen was taken from the body of a man who was said to have died from "cirrhosis of the kidneys." A second and similar specimen by its side had the same renal association. He agreed with Dr. Hale White that the ulcers were post-inflammatory rather than hemorrhagic erosions. In albuminuric retinitis the inflammation occurred first and the hemorrhages later. Dr. Church had not noticed the association of ulceration of the intestine with chronic Bright's disease, although he had frequently observed pigmentary changes in the intestinal tract. Dr. Dickinson, in reply, said that Sir William Gull might have known of the condition, but in the course of many conversations with him on the subject of renal disease he had never mentioned it. In his cases he had found no evidence of enteritis, and the hemorrhages were very deep in the wall of the bowel, and there were hemorrhages elsewhere in the bowel independently of ulceration. The ulceration was constantly associated with retinal changes and hypertrophy of the heart. Ulceration was rare, for it had only been met with in the post-mortem room at St. George's Hospital about twice a year. The pigmentation of the intestine was, he thought, due to hemorrhage of old date.

Mr. J. Hutchinson, Jr., then gave the particulars of a case in which abdominal section was performed for acute intestinal obstruction, due to multiple hydatid cysts, the cysts being removed and recovery resulting. The patient, a gardener, aged fifty three years, was seized with symptoms of acute obstruction three days before the operation. He had ascites at the age of thirty, which was cured by a single tapping. On abdominal section three hydatid cysts were found projecting from the peritoneum of the mesentery and extending in a row from the right of the umbilicus to the recto-vesical pouch, in which lay the largest of the three. They were of cartilaginous hardness and ivory whiteness, the largest being the size of a goose's egg, and apparently impacted in the pelvis. The cysts had walls one-third of an inch in thickness, contained numerous daughter cysts, and were in part calcareous. It was suggested that the attack of ascites, twenty-three years previously, gave the date of their deposit.

The case certainly presented uncommon features. The manner in which the hydatids were implanted in the position is not easy to understand. The great thickness of the walls might be partly due to the duration of the case. Such duration is now and again met with, and one was mentioned at the meeting which was diagnosed thirty-five years ago, and has not increased in size in that time, and was opened eighteen months since, and was found to spring from the under-surface of the liver.

It was suggested that the date of the deposit was that of the ascites, twenty-three years previously, and the long duration of such cysts is well known. One extending over thirty-five years was mentioned at the meeting, and it had not increased in size, but had lately been operated on in consequence of its setting up severe abdominal pain. It was attached to the under-surface of the liver.

It may be interesting to report, in succession to the foregoing case, another which was also related last week, but at a different society—the Clinical—at which Dr. W. J. Tyson gave his history of a case of suppurating hydatid cysts of the liver opened through the chest-walls in a woman, aged thirty-one. In 1888 she had a slight attack of jaundice, and again in January, 1892.

On admission to hospital, February 8th, the liver was found to be enlarged, extending below the ribs for four inches; all other organs healthy; the evening temperature was 101° F. A week after admission signs of pleuritic effusion into right chest developed, and the liver had now reached as far as the pubes; the evening temperature remained high. On February 27th twenty-three ounces of serous fluid were drawn off from the right side; on March 3d the posterior part of the chest was again aspirated, and an ounce of puriform hydatid fluid escaped. March 5th an incision was made into the eighth intercostal space, posteriorly, three inches in length. As soon as the pleural cavity was opened about an ounce of fluid flowed out, and an elastic swelling presented itself, the cyst-wall of which was stitched to the external wound; the cyst was then laid open and thirty ounces of thick pus, full of cysts of all sizes, escaped; the cavity was not washed out; a large India-rubber tube, six inches in length, was put in. External dressings of gauze and wool were then applied. There was no difficulty in putting in the stitches between the wall of the cyst and the skin wound, on account of the wide separation of the adjoining ribs. For three days after the operation about half a pint of pus and "skins" passed, and the cavity was washed out with boracic acid solution through the tube. On March 13th the breathing became audible over the base of the right lung, and the liver dulness had disappeared. The discharge gradually became

less, but the tube, although shortened from time to time, was not finally removed till February, 1893. The case, when first seen, was thought to be one of simple enlargement of liver; but the rapid increase in its size, with the high evening temperature, pointed to a suppurative condition of the organ. The presence of the pleuritic effusion is worth noticing. There was never a sign of the liver contents entering the thoracic cavity after the operation. In such liver abscesses as the one described the opening through the chest-wall, posteriorly, seems to be the proper route to take, as being more direct and better adapted for drainage.

Mr. Wallis suggested that it would have been better at first to have made merely an exploratory puncture with a hypodermic needle, and then, later on, to have excised a rib or two when they could have dealt radically with the hydatid. If the hydatids were still living, the cyst-wall could have been pulled out, or if suppurating, it could have been treated as an ordinary abscess.

Sir Dyce Duckworth objected to the practice of washing out these cysts, and preferred the policy of non-interference provided a sufficient exit were made, a large drainage-tube inserted, and the patient kept in a proper position and surgical cleanliness adhered to. He thought that the majority of hydatid cysts and empyemata did better under this plan than when washed out.

Mr. Hulke noticed that the abscesses which ruptured upward could be divided into two classes, viz., those in which the hydatid burst into the lung first and caused a secondary empyema, and those in which the rupture took place primarily into the pleura. In the first class there was decided risk in washing out, for these cases resembled an empyema communicating with a bronchus. In one case which had been irrigated with iodine, traces of that substance were detected in the expectoration. He believed that the introduction of a small quantity of iodoform emulsion would naturally assist in keeping the cavity sweet.

London, January 27, 1894.

On Monday last (22d inst.) there was a pleasant clinical evening at the Medical Society of London. A piece of rubber tubing was exhibited, eleven inches in length, which Mr. Gould has removed after making out its position with the cystoscope. Similar cases were mentioned in which the cystoscope had located the foreign body; one of these was a bit of a wax taper which, as it floated on the water, was by no means easy to seize with a lithotrite. Two men were shown for whom wiring of the patella had been done. The general opinion was in favor of wiring, but it was remarked that any suture could be used, but when wire was employed, patients might move about before bony union had taken place. Another exhibit was a man with a horn on the penis nearly two inches long, which developed a few months after circumcision. It was suggested that the outgrowth might be due to the accidental implantation of epithelial cells at the operation. This seems likely, as we know that similar growths occur in other conditions admitting such an explanation, *e.g.*, on the fingers where pins and needles may engraft the cells.

There was also a good show at the last meeting of the Pathological Society. Among the specimens was one of diseased vermiform appendix removed by Dr. Fred. J. Smith from the body of a man with no history of previous illness when he was admitted to hospital for acute nephritis. At the autopsy the kidneys were found enlarged, mottled, and adherent to their capsules. The stomach and intestines down to the colon were patched with red, but there was no ulceration. The appendix shown was pale and curved on itself by the contraction of adhesions; in its mesentery was a dark hemorrhagic swelling the size of a seed of nux vomica. It is curious that no symptoms of inflammation of the appendix had occurred, and this suggests that other cases may occur and not be observed, and we know that some recover under medical treatment. There were also specimens of cranial deformity in two infants associated with fusion of the fingers and toes; of pyæmic actinomycosis in man; and of aneurism of the aortic valve from a child of eighteen months who succumbed to capillary bronchitis coming on six weeks after measles.

Further I may mention two specimens of very extensive ulceration of the large intestines in their whole length. The patients—women thirty-two and thirty-six years of age—had suffered from uncontrollable diarrhœa for seven and ten weeks respectively.

Lord Coleridge "has put his foot in it," to use a proverbial expression. He seems to have permitted the antivivisection faddists to prey on his good nature, and, like others who have trusted them, finds too late that he has been taken in. Still the Lord Chief-Justice should have exercised a little judicial caution. Instead of that, having been shown a sentence in a little work on microbes issued by the Christian Knowledge Society, he wrote an intemperate letter, duly communicated to the newspapers, threatening to withdraw from that society unless the publication of the book in question was stopped. The committee, finding that the book merely touched on the question of experiment historically, and did not recommend, or even consider vivisection, declined to condemn it.

His Lordship accordingly withdrew from the society; others at once made up for the loss of the trifle he subscribed, and now it transpires that he has had to acknowledge that he has not read the book, but was only shown an extract.

It seems incredible that all sense of judicial impartiality should desert the Lord Chief-Justice of England when he puts off his wig and gown and leaves the bench. But this vivisection question seems to give rise to a sort of madness, and all who trust the good faith of the faddists seem to injure their reputation in parting with their common sense.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 10, 1894.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	0	0
Scarlet fever	129	16
Cerebro-spinal meningitis	0	0
Measles	594	19
Diphtheria	190	59
Small-pox	23	9
Cholera	0	0
Varicella	0	0
Pertussis	0	0
Erysipelas	0	0
Leprosy	0	0

Serum-therapy of Syphilis.—Bonaduce (*Monatshefte f. Prak. Derm.*, Bd. xvii., No. 3) has conducted a therapeutical study bearing on this subject. Blood was drawn from three children born with all the characteristics of hereditary syphilis. This was allowed to stand for a day on ice, and from it 35 c.c. of serum were obtained, to which 100 c.c. of sterilized water were added. This mixture was heated for ten minutes to 100° C., and was filtered. A patient, thirty two years of age, who had exhibited for eighteen days a characteristic chancre, in the coronary sulcus, and whose inguinal glands were typically enlarged, received injections of this serum in the subcutaneous cellular tissue. These were conducted with all aseptic and antiseptic precaution, and the injection fluid was kept aseptic. There was no inflammatory reaction excited. In all, twelve injections were given in twenty-four days; about ten cubic centimetres were administered at each injection. During this treatment the glandular enlargements subsided and the ulcer grew steadily better, although no local treatment was employed. After thirty-five

days the ulcer was completely healed and the inguinal adenitis was markedly lessened. The treatment was begun November 13, 1892, and at the time of the report (June 23, 1893) the patient was well and on the most minute search showed absolutely no signs of syphilis. It is suggested that blood may be used from the placenta of a syphilitic child, or may be taken from individuals who are at the height of secondary syphilis, but in all cases the serum should be employed with the most minute antiseptic and aseptic precautions. In Italy, Tommasoli has sometime since proposed a method of hæmo-therapeutics in the treatment of syphilis. This consists in the injection of serum derived from the blood of lambs or calves, the practice being based on the theory that since these animals are immune to the disease, their body fluids must contain some immunizing substance. Fournier has obtained some results from injections of the blood serum of the dog and horse, and Pellizzari has expressed the hope that by the injection of the blood serum of syphilitics who are in the transitional period between the secondary and tertiary stages of development all secondary lesions may be prevented in those who are suffering from chancre.—*Medical Review.*

The Methodical Examination of Pregnant Women in Private Practice.—Dr. J. Milton Mabbot says: "The most common utility of the practice recommended, consists in the conversion of podalic or pelvic into cephalic presentations in single pregnancies. The time of election is prior to labor, preferably toward the end of the eighth month, to secure the advantage of the presence of abundant amniotic fluid with unruptured membranes, and the absence of the contractions of parturition. Under these conditions it is not usually difficult to push up the breech and bring down the head by a procedure requiring no anæsthetic, and involving but slight discomfort to the mother, while it improves the prognosis of labor both for herself and for the child. And while infant mortality in breech labors is conceded, *cæteris paribus*, to be much higher than in vertex cases, additional danger to the cervix and perineum being also involved on account of the necessity for rapid delivery of the after-coming head, what right have obstetricians to neglect a means so simple and devoid of danger? Some one may raise the hypothetical objection that the practice recommended might occasionally result in a face or brow presentation, which would be more unfavorable than a breech. So far as I know, no one has yet raised such an objection or met with such a case. Attitudes resulting in face and brow presentations are not generally assumed by the fœtus until shortly before or during the first stage of labor. Such an unfavorable occurrence in breech cases subjected to version should certainly be no more common than among head presentations in general. In the rare cases in which it might be directly produced by version, it would probably be recognizable and remediable; and, furthermore, it is offset by the possibility of recognizing and counteracting conditions favoring spontaneous face and brow presentations which, without the examination, would have gone undiscovered and unremedied. The recognition and correction of breech cases are not the only field of utility of examination during pregnancy. The discovery of an anteverted or retroverted uterus susceptible of replacement, a uterine fibroma or carcinoma, an ovarian cystoma, or an ectopic gestation may reward early investigation. Face and brow cases (as just indicated), occipito-posterior positions of the head, oblique positions and unusual size of the fœtus, deformities of the pelvis, tumors, and other causes of dystocia or of danger, may be unexpectedly encountered. Some of the latter are as remediable, perhaps, at the commencement of labor as earlier. Even in such cases may not a previous examination make us better prepared to render the required assistance? In other cases, when we are called after the advent of labor it is too late, and we can only contemplate what might have been."—*New York Medical Journal.*

A Doctor's Troubles.—"My dear fellow," said my doctor to me, "you have no idea what we have to put up with. If I call to see a patient frequently, I am 'trying to run up a bill;' if I don't, 'it is shameful neglect.' If I manage to get to church, and am called out, I hear afterward, 'Working the Bob Sawyer dodge on Sundays, eh, doctor?' If I am so busy that I cannot go, I am sure to be asked, 'How is it that you doctors are all atheists?' If my wife calls on people, 'it is because she is trying to get patients for me,' but if she doesn't, it is because she is 'too stuck up.' If I cure a patient quickly—get credit, you say? oh, dear, no!—the patient 'wasn't half as bad as the doctor tried to make out; why, he was quite well in a week;' but on the other hand, should the case develop serious complications, 'Ah! the doctor never understood the malady; in fact, he was worse when he had been taking the medicine a week than when we called him in.' If I suggest a consultation, it is only because I don't know what is the matter; if I pooh-pooh the idea as unnecessary, I am 'afraid of showing my ignorance.' I am expected to, so to speak, cast a horoscope on a baby's life, and tell its mother what its ailments will be. If I can't do that, I 'cannot possibly know very much.' I am expected to foresee all the 'ills that flesh is heir to' six months before they come. I once lost a patient whom I had treated for influenza, because I did not foretell an attack of rheumatism which came on three months later. In all cases, if they get worse, the fault lies in the medicine; if they get well, it is 'the goodness of Providence.' If I send in my bill, they say, 'he is in a terrible hurry for his money;' if I don't, it is 'so unbusinesslike.' 'But we get well paid?' do you say. My dear sir, if I received payment for one-half I do, I should die from shock."

Horse-Hair in Minor Surgery.—Dr. C. O. Thompson writes to the *Boston Medical and Surgical Journal*, October 5, 1893, giving his experience with horse-hair in minor surgery. The objection has been made that horse-hair, being cellular in structure, cannot be sterilized. This objection, however, is not well founded, as horse hair is not materially injured by any of the methods used in the sterilization of dressings. Boiling in water is acceded to be one of the most practical methods; and according to experiments all pyogenic bacteria are quickly destroyed, even the spores of these organisms cannot long resist this treatment. It is, therefore, an easy matter, should sutures not be at hand, for one to always readily prepare a practically sterilized suture, by removing a few hairs from the tail of a horse, placing them in boiling water for from three to five minutes, when they will be ready for use. In preparing the hair a bundle of one to four drachms weight is freed from dust as much as possible, and then washed in a strong soap or soda solution. When dry it is transferred to an ordinary pint fruit jar, which is filled with benzine and frequently agitated to remove all fatty material. Finally, it is rinsed in a strong bichloride solution and kept in the same (1 to 1,000). Experiments made with hair thus prepared have shown that it is absolutely sterile. Dr. Thompson describes the different purposes for which he uses horse-hair. They run from a simple cut up to a ruptured perineum. He summarizes its advantages as follows: 1. Easily obtained and inexpensive. 2. Soft, pliable, elastic, and holds a knot well. 3. Aseptic, non-absorbent, and non-irritating. 4. Can be used with a very small needle, and makes no shoulder at the eye. 5. More easily removed than any other suture, without pain or injury to the tissues. 6. Can be used for drainage.

Education not Appreciated.—A young doctor, desiring to make a good impression upon a German farmer, declared he had received a double education: He had studied homœopathy, and was also a graduate of a "regular" medical school. "Oh, dot vas nodding," said the farmer; "I had vonce a calf vot suckd two cows, and he made nodding but a common schteer, after all."

THE CURE OF CANCER BY OPERATION.[1]

BY B. FARQUHAR CURTIS, M.D.,

ATTENDING SURGEON TO ST. LUKE'S HOSPITAL, AND TO THE NEW YORK CANCER HOSPITAL.

WHAT is to be considered a cure in a case of cancer? We can scarcely talk of a cure so long as there is any danger of recurrence, and it is exceedingly difficult to set a time limit when that danger shall have passed. The great majority of recurrences appear within the first six, or at most twelve, months after operation, but many come in the second year also, and a few in the third. After that date recurrence is not common, and yet quite a number of cases are on record in which a recurrence has taken place even later.

I do not include among the cases of recurrence those in which the disease returns at some other point in the body, at a date too late to make it probable that we have to deal with a metastasis from the original tumor, as in two cases of mammary carcinoma reported by Eder, in which the same disease appeared in the other breast four and seven years, respectively, after removal of the first. But true late recurrences are not uncommon. Plicque has collected thirteen cases of relapse after an interval of three years. Schmidt reports three cases of cancer of the breast relapsing in the fourth year after operation, one in the sixth, and one in the seventh. Fink reports three cases, Hildebrand two, Dietrich three, and Poulsen eight, cases relapsing after three or more years. Partsch reports two cases of cancer of the lip recurring eight and ten years after operation. Fraenkel reported recently a case of a comparatively young woman, thirty-seven years of age, who had been under constant observation for eight years after a high amputation of the cervix uteri for epithelioma, and who finally developed a recurrence in the body of the organ. Then there is the well-known case of laryngectomy done by Hahn, in which the patient remained well for eight years, and finally developed another cancer in the scar. In the rectum late recurrence appears to be especially common, cases having been reported by Volkmann, König, Kelsey, Böckel, Arnd, and Lövinsohn, of recurrence at intervals of from three to eleven years. The tongue also appears to have a bad prognosis in this respect, recurrences after an interval of more than three years being reported from Billroth's and Volkmann's clinics; while Kocher had the misfortune of seeing a return in two of his cases ten and twelve years after operation. The same surgeon saw return of the disease in the scar after laryngectomy, in four cases, three years after the operation, and Billroth and Fischer had similar experiences.

Metastasis has usually been supposed so show itself very soon after the primary operation, if present at that time, but there are some cases on record which go to prove that it may fail to declare itself for some years. One of Poulsen's cases of cancer of the breast died of cancer of the stomach over five years after the operation on the breast, and three others died with signs of some internal recurrence in from three to six years. Schmidt reports a case of death by cancer of the lungs and liver seven years after removal of the breast, and Dietrich one in the uterus four years after a similar operation—in neither case was there any local return. Lövinsohn reports a case of cancer of the rectum which did not return in loco, but the patient died four years later of metastasis in the liver. The last case is perhaps not so very remarkable, for the liver infection might itself have been secondary to disease in the lymphatic glands, and thus not have been very much longer in developing than usual. Some of the other cases can be explained as the growth of entirely independent tumors, and I should certainly so interpret the cases of late appearance of the disease in the other breast, and of pyloric cancer. But there still remain some cases of recurrence in the lungs and liver which appear to be true developments of secondary tumors.

It is, therefore, self-evident that the limit of two years set by the earlier writers is altogether too short to assure a cure, and it may even be questioned whether the limit of three years can be allowed to stand. It is true that the number of cases of malignant disease occurring three years and more after the operation is very small, but it should be remembered that the proper basis of comparison is not the number of operations, but the number of patients who remain alive and free from disease three years and more after the operation, and that number is comparatively small. Thus my lists give me one hundred and eighty patients alive and free from recurrence for three years or more after removal of the mamma for carcinoma (cancer); and they also give me twenty-three cases which relapsed after that period—or thirteen per cent., a comparatively large proportion. Certainly, for the rectum, the tongue, and the larynx, a four years interval of freedom should be required before a case can even relatively be said to be cured. Taking all these facts into consideration, we have taken three years freedom from recurrence before allowing that a case is cured, and for certain organs we have set the limit at four years.

It is, in fact, true that the expression "cure" can hardly be employed in a strict sense. A fair idea of the matter can best be obtained by considering the somewhat parallel case of the chronic infective inflammations. Take, for instance, the now well-understood tuberculosis of bones and joints. If a child has a tubercular arthritis of the knee, a cure may be brought about by immobilization and general treatment, the infective material and the products of surrounding inflammation being partly absorbed and destroyed by the surrounding tissues, partly encapsulated. Even when this has taken place it is uncertain whether the cure is permanent or not, for relapses are common, and they may occur even after half a lifetime. These relapses can be explained by the supposition that the encapsulated infectious material has been awakened to life—perhaps some blow or other injury has burst its capsule, or perhaps the general condition of the system has suffered and the encapsulating tissues have lost their vitality and power of resistance, and so allow the enclosed material to resume its growth. In case of an outbreak of disease in another joint, it is rather simpler to assume a reinfection from without. In either case we need not fall back upon the ancient and worn-out theory of a diathesis or dyscrasia, although we may admit the predisposing influence of certain constitutions. So with cancer, whether we look upon the cell itself, or some special infection or parasite as the local cause of the disease, in every case it is a true infectious agent; and although we have as yet no positive evidence that cancer can remain encapsulated without growth in the tissues for any length of time, yet there are some facts at our dis-

[1] Read before the New York Clinical Society, January 26, 1894

posal to show that the supposition is at least a possible one. We have, in the first place, the occasional but apparently well-authenticated reports of the spontaneous disappearance of apparently malignant growths, and even Virchow admits the possibility of this occurrence. But more important is the every-day fact of the dying out of cancerous infiltration followed by healthy cicatrization of the skin along the edges, as seen in that form of epithelioma known as Jacob's, or rodent, ulcer. If the tissues can overcome the cancerous infection in such cases, it is certainly reasonable to suppose that, under favorable circumstances, they should also encapsulate them. Indeed, to my mind the very fact that we can eradicate and "cure" the insidious and spreading cancerous growth by our operations—which, no matter how broadly planned and thoroughly executed, are very crude methods of dealing with such an insidious foe—makes the analogy with tuberculosis even closer. The thoughtful surgeon can hardly close a wound after an operation for tuberculous disease of bones or joints without feeling certain that, in spite of his best efforts, his operation has been far from ideally complete; for there are probably small foci which he has not been able to recognize and has left behind, while he has undoubtedly inoculated his fresh wound surface at many points with tuberculous material which he has been attempting to remove. Nevertheless, he hopes that he has created an opportunity for recovery, because he knows that the healthy tissues will be able to dispose of or encapsulate the few remaining bacilli. It is, I believe, because of a similar power of resistance of the tissues to the infectious material of cancer, but of course to a hundred-fold less degree than in tuberculosis, that we owe our ability to cure cancer by operation, and the same theory gives some explanation why late recurrence is frequent in cancer as well as in tuberculosis.

To ascertain the results of the treatment of cancer by operation we are dependent upon the statistics offered by the various large clinics, especially the full reports of the German and Swiss surgeons. To collect cases at random from the literature, would expose us to many fallacies. Therefore, I have rejected this method, especially as statistics so collected are apt to be too favorable, the unsuccessful cases usually not being published. I have consequently taken only those cases which are published in series by reliable men, so that I should be reasonably sure of getting all the cases in the experience of the particular surgeon. I have, as far as possible, taken these cases from original reports, not accepting the analyses of other students of the subject, or even of the reporters themselves, without investigation.

In order to combine or to compare the results of different operators, it is necessary to agree upon some standard method of analyzing the cases. To obtain the most reliable percentage of cures by the accepted limit in any set of cases, we should know the total number of operations performed before the limit of the time agreed upon, whether three or four years, and use that total as a basis of reckoning; for it is evident that, if all the cases operated upon up to a certain date are taken, and the number of cases which have remained well for three years reckoned as a percentage of the total number, the result will be unfair, because the unfavorable cases (those with recurrence) count on the debit side, while there are a number of cases free from recurrence, a certain proportion of which will remain well and ultimately count on the credit side; but as they have not passed their crucial period of time, they cannot as yet be so counted.

The next step is to deduct from the total all cases, free from recurrence when last seen, which have died or have been lost sight of before the time limit of three or four years passed. Some authorities deduct also all cases which have died from the operation—a proceeding which is, as Gross says, incorrect; and yet it is hardly fair to include them, for some of these fatal cases would be balanced by the cases lost sight of before the limit expired, and if the mortality were heavy and there were also a large number of cases lost sight of, the result would be very far from the truth. To take an extreme case, suppose that half of the patients should die from the operation and half of those who recovered were lost sight of, while of the remainder one-half were cured, if the percentage were to be reckoned only on those who recovered and were followed, the cures would amount to fifty per cent.; while if it were calculated on the total number, less those lost sight of, it would make less than seventeen per cent. It is evident that the truth lies somewhere between these extremes, for, if the total results of all these cases could be found, and if the results of these unknown cases corresponded, as they probably would, to those of the cases followed, the proportion would be twenty-five per cent. of cures. In other words, when patients are lost sight of, it is as if they had not been operated upon at all, and if there had been less cases operated upon and there would have been fewer deaths consequently, these cases should have deducted on their account a certain part of the fatal cases. The importance of this distinction depends entirely upon the rate of mortality, and when it is low it makes very little difference whether the fatal cases are included in the basis of percentages; and in stating the results of my calculations I will quote both figures.

I shall limit myself in this paper to a consideration of carcinoma (including epithelioma) of the larynx, tongue, rectum, breast, and uterus, as full statistics are not yet on record for other organs.

Larynx.—In the treatment of cancer of the larynx we have one of the battle-grounds between the specialist and the general surgeon. The statistics, so far, are rather against the latter, but they really prove little except that the cases are subjected to radical operation too late, and as has already been the case with the uterus, early diagnosis and prompt operation are likely to improve them at any time.

I have collected cases from the reports of the clinics of Fischer[1] (thirteen cases), Hahn[2] (seventeen cases), Billroth[3] (twenty one cases), Trendelenburg[4] (five), Krönlein[5] (six), Schede[6] (three), and Kocher[7] (ten)—a total of seventy-three cases with twenty-two deaths — almost exactly thirty per cent. In twenty-seven total laryngectomies the mortality was 40.7 per cent., and in thirty-seven partial laryngectomies the mortality was 21.6 per cent. But we must not jump at once to the conclusion that this is a true picture of the relative danger of the two operations, for it is to be remembered that the early operations were chiefly complete, while the partial operations belong to more recent times and benefit by the improved technique. Strangely enough, in Kocher's ten cases he lost only one of six total extirpations, and two out of four partial ones. In any case the mortality is very heavy, and yet it is a mortality which can certainly be reduced, as is shown by Kocher's low mortality in spite of the extensive character of his operations.

Twenty-two cases of total extirpation were followed, of which eight recurred in the first year, fourteen in the second, one in three years, and one (Hahn's famous case) recurred after nine years of health; the rest being free from recurrence—five for a few months, two for two years, and one for four years and more. Of the partial laryngectomies twenty-nine were followed, thirteen recurring in the first year, five in the second, one after three years; while of those free from recurrence it was known that six cases were healthy for a few months, one for one year, two for two years, and one for three years. In each set three cases remained well over two years. Of the complete operations, excluding Hahn's case, we have 13 6 per cent. remaining well over two years, and of the partial operations 10.3 per cent. Both combined make 11.7 per cent. But if we apply the usual three-year limit,

we find only three cases cured, even including Hahn's, amounting to 5.8 per cent., the worst result of all operations for cancer, except in the internal organs. But the operation has not as yet had a fair trial, as is evident from the fact that recurrence is so frequent, although it is well known that in this form of cancer the glands are very late in becoming involved. I believe that the ultimate results here should certainly equal those in the tongue, and the mortality ought not to be much higher.

Tongue.—Several important reports upon the result of operations for cancer of the tongue have been published during the last few years. Whitehead [1] furnishes us with statistics of 129 cases, Billroth,[2] 139, Volkmann,[3] 91, Czerny,[4] 28, König,[5] 28, and Kocher,[6] 58—a total of 473 cases, with a mortality of 54, or 11.4 per cent. From those reports which are so particularized as to give the exact kind of operation performed, we find that the entire tongue was removed in 139 cases, with a mortality of 15.8 per cent., and that removal of one-half or less of the tongue was accomplished in 81 cases, without a single death. The removal of the tongue through the mouth, with no preliminary operation except ligature of the linguals, was performed 163 times, with a mortality of 12 8 per cent., and 77 times the organ was removed by Kocher's method, or after resection or division of the lower jaw, with a mortality of fourteen per cent. This slight difference in mortality should be noted, for it is contrary to the generally accepted opinion, that the so-called simpler method of excision with the scissors is a much less dangerous operation than the other methods. Whitehead states the mortality of extirpation of the tongue with simultaneous removal of glands, in his hands, to be seventy-seven per cent. in the small number of cases in which he has tried it; and with such bad results it is not wonderful that he should advocate the simple scissors operation through the mouth; but his results are so much worse than those of other operators, that it is evident that he attempted operation in cases unsuitable for any interference. A fairer estimate of the comparative danger of these operations can be formed from Kocher's cases recently published. From 1872 to 1882 he operated twenty-nine times, with five deaths, and from 1883 to 1888 twenty-nine times, with only one death, showing what practice will do in improving technique, and very likely also what experience can effect by selecting cases. He removed the tongue through the mouth without preliminary operation except ligature of the linguals, in eighteen cases, without a death, but when Kocher selects this method of operating it means that the case is a very favorable one. He operated by his own method in twelve cases, with one death (8.3 per cent.), and by division of the jaw or in cases requiring partial resection of the jaw on account of disease, in twenty-two cases, with four deaths (18.1 per cent.). The last group includes very severe operations in unfavorable cases, for Kocher seldom operates by division of the jaw unless the disease is so extensive as to require partial removal of the bone. These figures give, it seems to me, a true view of the choice of methods and of the results to be expected from each.

Now, as to final results. In our table the final result is known in 186 cases, recurrence taking place in 111 (39 in six months, 26 in the second six months, 16 in the second year, and 30 in three years or more), and of those without recurrence 51 were followed for less than three years, 8 for three years, 16 for four years or more. At the three year limit this gives us ten per cent. of cures, and at the four-year limit 6 6 per cent. If we deduct from the total the fatal cases these figures become 13 and 8.6 per cent., respectively.

There were two recurrences among Kocher's cases at ten and twelve years after the first operation. Among his operations are included many very severe ones, and Sachs, in studying the effect of this upon the final result, finds that in eighteen cases living one year after the operation, it had been severe in seven; of thirteen cases living two years, it was severe in five; in eight living four years, severe in four; and in five living seven years, it was severe in three. Wölffler had claimed that recurrence took place later in those cases in which the operation had been extensive, but Kocher's statistics show that in eight such cases recurrence took place in 5.1 months, while in fourteen cases limited to the tongue itself, recurrence occurred in 8.3 months, which seems more probable, for extensive operations mean extensive disease, difficult to eradicate completely. Yet, from the figures just given, Kocher appears to have been so successful that more than one half of his long-lived cases had been subjected to severe operations. Of all the cases which remained free for one year or more, ten in number, there were severe bone operations in three, and in five glands were removed, while only seven were operated upon through the mouth.

By way of comparison we quote Whitehead's statistics, which are also excellent. He reports seventeen cases surviving less than three years, two for three years, five from four to ten, and one over ten years, making twenty-five cases out of a total of 129 operations, most of the rest not having been followed.

Rectum.—Reports on the results of treatment of rectal cancer lie before me from the clinics of Kocher [1] (35), Cripps [2] (38), Czerny [3] (109), Genzmer [4] (17), König [5] (54), Esmarch [6] (29), Albert [7] (39), v. Bergmann [8] (46), v. Wahl [9] (18), Krönlein [10] (20), and Billroth [11] (15), a total of 420 operations with a mortality of 15.5 per cent. It would be desirable to completely separate the operations done from the perineum from those in which the sacrum was attacked, but I have been unable to do this to my satisfaction, owing to the manner in which the two have been confused in the reports. For a careful study of mortality and results, the operations on the rectum should be classified under a double division, first as to the part of the bowel removed, second as to the mode of attack, whether the entire circumference of the bowel is removed or only a part, and whether excision is made high up without affecting the anus, as in the resection, or whether it removes the entire lower segment, as in amputation: for all of these points affect both the mortality and the later results. But there are not as yet enough cases available for a complete study of this kind.

As to the mode of attack, the decision of the question as to the value of those methods of operation which divide the sacrum is most important. The method advocated by Kocher, of making a posterior incision from the anus to the base of the coccyx and removing this bone, amounts to a prolongation of the ordinary incision, and does not complicate the ordinary perineal operations sufficiently to require separate consideration. But the true sacral methods add an extensive injury to the bone, with all the increased dangers of prolonged operation, sepsis, and hemorrhage, and it also brings within the scope of the operation many cases of extensive disease which could not otherwise be attacked; consequently it is natural to expect a higher death rate and a greater percentage of relapses. Czerny, in reporting his cases, does not distinguish between cases operated upon according to Kocher and Kraske, and this appears to me an error.

In estimating the final results we shall do well to accept the four years limit as the test of a cure. Taking the sacral and perineal operations together, of the 420 cases in my list, 144 were operated upon four years before the report, thirty-three died from the operation, and 13 were lost sight of, leaving 99 to test the question of recurrence; and of these 99 recurrence took place in 71 before the four years elapsed, while 28 remained free from the disease. Calculating on the total number, including the fatal cases but excluding the 13 lost sight of, the percentage of cures is 21.3 per cent. We might add that 4 healthy cases of Krönlein's only lacked from three to six months of the four years at the time of report, consequently they were not included; while 3 of Czerny's cases were attacked again by the disease three, four, and seven years after the first operation, so that they had to be placed on the debit side of account; therefore our estimate is certainly not biased in favor of the operative results.

The majority of these cases were perineal operations, and nearly all of the cures were the result of such operations. But it must not be imagined that for this reason the operations were slight or the cases all favorable. I have especially studied this point in the histories of forty-three cases of cures (estimated by the four-year limit) which were accessible, with the following results: Twenty might be called favorable cases, being tumors low down or with small attachments, but the rest were all serious, while in eight cases the operations were extensive and severe. For instance, in the last category we find twelve to eighteen centimetres of bowel removed in several cases, the vaginal septum infiltrated and removed, the prostate attacked and seminal vesicles partly removed, and finally a large tumor filling the rectum, involving the vagina and compelling the opening of Douglas's pouch, and the use of the curette on masses there which could not be cut away. One case of Esmarch's was a melanotic tumor, which occurred in the inguinal glands later, but after removal there did not recur, the patient remaining well seven years after the first, and five after the second operation.

Breast.—In the last five years reports have come from the clinics of Czerny[1] (104 cases), Gussenbauer[2] (153 cases), Küster[3] (222 cases), v. Bergmann[4] (114 cases), König[5] (152 cases), Lücke[6] (148 cases), Copenhagen,[7] Paulsen reporter (280 cases), and Angerer[8] (40 cases)—amounting to 1,213 cases operated upon for cancer of the breast since 1870. Of these, 71 cases died, a mortality of very nearly six per cent. Of those that recovered the subsequent history has been ascertained in 813 cases, as follows: Two hundred and eight recurred within the first six months, 88 during the second six months, 56 during the second year, besides 35 other cases in which the date of recurrence is unknown; a total of 633 recurrences. The rest remained free from recurrences, eighty-eight for less than three years, 180 for three years or more, including forty-five cases over four years, and three cases over ten years. If we calculate the percentage of cures, accepting the three-year limit as a text, we find that twenty-two per cent. of the cases followed remain well for that length of time. I am at a loss to explain the sudden falling off in the number of cases followed four years and over (45 cases), as compared with those of three years, even bearing in mind the high normal death-rate among persons so advanced in years as these patients usually are (averaging fifty years at least), for there are only twenty-three recurrences after the three year limit. Probably it is due to the fact that the reporters have not made the same effort to keep in sight patients whom they have supposed to have reached the limit of safety, three years being so commonly accepted as that limit.

[8] Bihler: Dissert., Centralbl. f. Chir., 1890, 869.

We may compare with these results the work of some of our own surgeons, although, as full details have not been published, I have been unable to include them in my tables. Dennis reports the results of 33 cases of amputation of the breast for carcinoma with no deaths, and twenty-five per cent. of cures; and Weir, in a series of 125 cases also with no mortality, states that twenty per cent. of the 60 cases which he was able to follow for three years had no recurrence. Angerer, in 40 cases, had a mortality of zero, and Poulsen gives the Copenhagen mortality as only 5 in 280 cases, less than two per cent.; and these are the lowest rates of the foreign operators.

I have taken, from the original records of such reporters as were accessible to me, the totals of all cases operated upon more than three years before the report—in other words, all those cases which had a chance to remain free from recurrence for that time. The sum of these totals is 826 cases, of which 59 died from the operation and 767 recovered. Of the latter 154 remained well, 529 had local recurrence or metastatic growths, and 82 were lost sight of or died of other causes in less than three years. Deducting the last set of 82 cases, we have a percentage of cures of 22.5 on the basis of the recovered cases only, or including the deaths, a percentage of 20.7 on the total number of cases. In either case the result is better than one patient in five cured.

It would seem unnecessary at this late date to dwell upon the necessity for clearing out the axilla in every case, whether the glands can be felt there or not; but since such authorities as Butlin and Treves still defend the old idea of leaving the axilla untouched unless glands can be felt, I must emphasize again the teaching of Volkmann, Banks, and Gross. Gross found, in those cases subjected to operation in which the site of recurrence is noted, that in 96 cases operated upon without touching the glands, the disease reappeared in the cicatrix or vicinity alone in forty-eight per cent., in the axillary glands alone in twenty per cent., and in both in thirty two per cent., returning therefore in the glands in fifty-two per cent. of the cases. On the other hand, in 313 cases in which the axilla was also cleared the percentage of recurrences was seventy-five locally, twelve in the glands, and thirteen in both, a reduction of the glandular recurrences from fifty-two to twenty-five per cent. Surely one could have no better evidence than that of the influence which clearing the axilla exerts in preventing recurrence. As to recognizing disease of the glands through the skin, Gross states that they may be expected to be diseased even when they cannot be felt, as he found them affected in 14 out of 16 cases in which he could not feel them; while Küster found them affected in 57 out of 65 cases in which he could not feel them.

Uterus.—The results of treatment of carcinoma of the uterus have very greatly improved of late years, and we are now in possession of sufficient material to make a preliminary statement at least of these results. From the clinics of Shauta,[1] Landau,[2] Gusserow,[3] Olshausen,[4] Martin,[5] Leopold,[6] Hofmeier,[7] Boldt,[8] F. Krug,[9] Fritsch,[10] Kaltenbach,[11] Fehling,[12] and Terrier and Hartmann,[13] I find reported 798 cases of vaginal hysterectomy; and from those of Czerny,[14] Schede,[15] and Hochenegg,[16] 53 cases of the sacral extirpation of the uterus for carcinoma.

The mortality after vaginal hysterectomy is 9.7 per cent., but in the hands of some operators it falls as low as five per cent. Of the cases which recovered, 490 were followed, and 198 of these recurred, while 192 were well but had not yet passed the three-year limit, and 100 had passed that limit in safety; therefore there were 26.4 per cent of cures, or, deducting the fatal cases, 33.4 per cent. of the cases which recovered from the operation and had not been lost sight of, were cured. From the same sources I have been able to classify separately a list of all the cases operated upon by certain of the operators (Fritsch, Fehling, Terrier and Hartmann, Schauta, and Leopold) previous to the three years preceding the report, thus excluding all cases which had not had the opportunity to reach this limit; making a total of 156 cases, 15 deaths, 20 lost sight of, 60 recurrences, and 61 cures. This gives a proportion of cures equal to 44.8 per cent. of the cases followed, or 50.4 per cent. of the cases which recovered. This list includes the much criticised results of Leopold, but it also includes the rather unfavorable cases of Terrier and Hartmann, and even if we omit Leopold's cases, the figures still remain 35.8 per cent. of cures, or deducting the fatal cases, 41.3 per cent. The result, therefore, of vaginal hysterectomy for cancer can be said to be unusually good, certainly better than those of operations upon the breast.

The sacral method in extirpation of the uterus has been demonstrated to be feasible, and the mortality has fallen, so that Czerny lost only one in eight cases—although, to be sure, Schede, operating apparently in more desperate cases, lost 8 cases out of 28. I have found only 2 cases of cure in the 53 on my list. The utility of the method is doubtful, for as a rule, when the infiltration has extended so far as to contra-indicate vaginal extirpation, even the sacral method of attack will not completely eradicate the disease. Those unusual cases in which the infiltration extends backward, and not into the broad ligaments, are the only ones in which the method can claim any natural rights.

Abdominal hysterectomy for cancer, although much more often done than formerly, and with a constantly decreasing death-rate, has not as yet enough cases to its credit to enable one to speak authoritatively as to its merits.

The only operation which competes seriously with vaginal hysterectomy is supra-vaginal amputation of the cervix. Winter,[1] including Schroeder's cases already published, found in 155 cases a mortality of 10, but in the last 64 cases there was not a single death. Excluding 4 cases operated upon within three years, we find 151 cases with 10 deaths, 80 recurrences (13 which had passed in safety the third year after operation), and 46 free from recurrences for three years or more. Omitting the cases lost sight of before the three-year limit, the cures amount to 32.4 per cent., or 34.8 per cent. of the recoveries. This is not quite so good a result as that just given for vaginal hysterectomy, even when Leopold's favorable showing is omitted.

Byrnes[2] has recently claimed to have done 359 high amputations of the cervix with the cautery within twenty years, and to have had only 2 deaths; while 138 cases remained well for three years or more out of 201 who were followed for that length of time. This would give a proportion of 68.6 per cent. cures, a truly unheard of result. Unfortunately he does not seem to have verified his diagnosis by microscopic examination, so that it is not impossible that these brilliant results may prove somewhat overdrawn. It is impossible to conceive how hot steel can be more effective than cold steel in giving a greater freedom from recurrence. Certainly there is not so much tissue removed or destroyed in his operation as in a properly performed vaginal hysterectomy.

Operations for Recurrence.—After the facts we have been obliged to record of late return of the disease, either *in loco* or as metastasis, and of repeated returns after operations, it is necessary to throw a little more emphasis on the cheerful side of the picture by noting the comparatively large number of cases in which a cure has been established after a second or even several secondary operations. Plicque has put on record ninety seven such cases collected from various sources, but unfortunately I have been unable to obtain his thesis for study. But Poulsen records three cases in which two or more recurrences of mammary carcinoma were removed in the first year or eighteen months, and yet the patients remained well eight and nine and a half years after the last operation. He also mentions two cases in which recurrences appearing three and five and a half years after the first operation were successfully removed and the patients continued well respectively two and three and a half years later. Gouley relates two cases of very late recurrence of carcinoma of the breast (twenty and twenty-five years after the first operation) which remained well five years after the last operation, and a similar case of sarcoma. Parker records a case of amputation of the thigh for sarcoma recurring after amputation of the knee, in which the patient was well seven years after the second operation. Michael saw an epithelioma of the skin of the thigh recur twice, and finally remain well nine years after the last operation. Similar cases in the rectum are on record by Turner, Volkmann, and Arnd. I have met with a personal experience which is very interesting in this respect. In January, 1890, I removed a slow-growing epithelioma from the floor of the mouth in a man forty-nine years of age, removing at the time all the mucous membrane of the lower surface of the tongue and all the tissues between the mouth and the skin under the jaw, leaving the tongue above and the skin below. The bone was not affected at the time, but before he left the hospital a small growth had to be curetted from its inner surface. In December of the same year he returned with the lower jaw involved, and with a mass as large as a hen's egg over the great vessels of the neck, on the same side. I found a large gland adherent to the internal jugular vein, and excised with it over an inch of that vessel, otherwise the mass was not adherent; and two weeks later, when the wound had healed, I removed the right half of the body of the lower jaw with the diseased tissues attached. He made a good recovery, and now, three years after the last operation, still remains perfectly well. Perhaps it would be well to record here a case in which I removed the left breast and cleared the axilla in a woman thirty-seven years of age, at St. Luke's Hospital, in October, 1889, for carcinoma. In October, 1890, she returned with a nodule in the scar, and finding the latter very adherent and suspicious, I removed the entire pectoral muscle with it on that side. In December, 1892, she returned with extensive disease of the right breast, requiring its removal together with the pectoralis major of that side. It may be well to note in passing that the deformity in this case, after removal of both pectoralis major, was by no means striking, and the loss of function very slight. It is rather early to record this case, but she has, at all events, had four years of freedom from return of the disease upon the left side.

Summary.—To recapitulate, we find a proportion of cures in the larynx of 5.8 per cent., in the tongue (four-year limit), 6.6 per cent., in the rectum (four-year limit), 21.3 per cent., in the breast, 20.7 per cent., and in the uterus, 35.8 to 44.8 per cent.

Such are the results of the operative treatment of cancer. In spite of the general and great improvement over those of former times, it must be acknowledged at the outset that even free removal is no sovereign remedy for the disease. It may be said with truth that, if the disease is attacked in time it can be cured by a radical operation, but that single limitation prevents the universal success of operative treatment; for there must always remain the internal cancers that do not give symptoms until they are too far advanced to be completely eradicated, and also a large proportion of external tumors that, owing to the carelessness or ignorance of their vic-

[1] Winter: Archiv f. Gynäkol., xl., Hft 2.
[2] Byrnes: Trans. American Gynecol. Soc., 1892, xvii., 3.

tims, are not observed until it is too late for successful operation. As Winter puts it, supposing that one case in four of uterine cancer can be cured by operation, and only one case out of four which come to the surgeon is suitable for operation, we can save only one woman in sixteen of those attacked by the disease. We must, therefore, still desire a remedy which can cure the disease in any stage and in any situation, without damage to the surrounding parts, in some such way as mercury and potassium iodide act upon the lesions of syphilis; and there appears to be some ground for hoping for an advance in this direction since the experiments of Fehleisen, Sprouck, and Coley[1] have shown that, at least in some cases, it is possible to check the progress and even cause the absorption of malignant tumors by inoculation with the germs of erysipelas, or by hypodermatic injection of the sterilized products of cultures of that germ.

In the meantime let us hold the advantage we have gained and try to improve it, as can undoubtedly be done. The first step toward the improvement of these results must come through the family physician—the general practitioner. Not until he is fully convinced that operation will cure the disease if attacked in the early stages, and not until he is able to make an early diagnosis, can we secure the full value of this method of treatment. On him depends the entire question. Winter[2] interrogated fifty-six patients with uterine cancer applying at the Frauenklinik, in Berlin, and found that forty-seven of them had first had advice upon their symptoms, which were often vague enough at the beginning, from their family physicians, and yet only one-third of the number reached the clinic in time for useful operations. The reason was evident on closer questioning, for in only one half of the cases had the attending physician made an immediate examination of the parts, and in one-third of them no examination whatever had been made. It is not surprising that of this last set of fifteen cases, only three were found suitable for an attempt at operative treatment.

The same holds true of the breast. In a very considerable proportion of cases seen by me the patients have told me that their physicians examined the tumor in the breast, and declared that it was of no importance, that it would pass away, or would not grow larger, or even advanced that everlasting false explanation "it is the change of life." Now, it appears improbable that all of these physicians are so ignorant or so negligent as not to consider the possibility of cancer, and I believe that the chief reason for delay and neglect in such cases is the lack of faith in operative treatment, which will not only prevent the physician from urging early operation, but will act indirectly and lead him to neglect the proper study of a disease which he considers incurable, or at least to slight the examination and diagnosis of the cases in which he suspects it.

That this state of affairs is improving has also been shown by Winter, who states that, whereas in 1883 only nineteen per cent. of the cases of uterine cancer were considered to have enough chance of cure to make an operation worth while, in 1891, thirty seven per cent. of the cases were operated upon, and solely because the patients came at an earlier period of the disease. But it requires much further improvement before really good results can be obtained. The delay on the part of the physician occurs most often in waiting to have his diagnosis made certain, waiting for evidence of growth in the tumor, or for glands to enlarge, before he has the courage to suggest operation. As a matter of fact his attitude should be the reverse, and whenever he is not absolutely certain that a tumor is innocent, he should recommend operation, or at least seek the advice of those experienced in such diseases. Now that we are able to so easily remove small portions of a growth, and have an authoritative opinion upon its structure, a positive diagnosis can usually be made comparatively early, and the physician should remember that the very symptoms which he waits for in order to make a diagnosis, are usually such as indicate that the disease has already passed the favorable time for treatment—involved glands do not indeed contra indicate operation, but they show that it has probably gone so far as to greatly diminish the chances of cure.

The ignorance and cowardice of the laity will, of course, always limit our efforts to obtain more favorable conditions for really curative operations, but improvement in this respect is also largely in the hands of the profession, whose power and duty it is to educate the public, to show them the importance of having competent advice and prompt treatment for all swellings, tumors, warts, ulcers. and slow healing wounds, no matter how painless or trifling they may appear.

[2] Winter. Berlin, kl. Wochenschr., 1891, No. 3.

SHOULD THERAPEUTIC FASTING BE TERMED STARVING?—ITS EMPLOYMENT IN TYPHOID FEVER AND OTHER DISEASES.

By CHARLES E. PAGE, M.D.,

BOSTON, MASS.

THERE is a tendency among medical men to fall into ruts—the employment, for example, of a selected few of the all too many drugs at our disposal; the use of the milk diet for all diseases, or the "hash" and hot-water regimen (so efficient in appropriate cases), etc.—a tendency which is well illustrated by the story of the specialist who gave all his patients something to throw them into fits because, he said, he was "death on fits!" I have always regarded this story as probably apocryphal, until within a few months having read of a series of experiments (*The Post-Graduate* for August, 1893) in the "Treatment of Inoperable Sarcoma by the Toxic Products of Erysipelas," I think the "fits" story may be gospel, pure and simple.

One physician will bowl along for a time with quinine, antipyrine, morphine, and two or three other drugs, and pat himself on the back for his success, if he has chanced to have a run on a class of patients who were too tough to kill; but by and by he happens upon a succession of tenderlings, signs a lot of death-certificates at short intervals, when he begins to take a lively interest in the advertisements of the newer "specifics."

It is this condition of affairs, chiefly the fault of the medical schools, as it seems to me, that has cast the deepest shadow upon the bath-treatment (Brand), its advocates being regarded as faddists by the great body of strictly medical men. Only the rare few, the thoughtful students of methods, understand the true nature of this remedy. Only these can comprehend why it is any less queer to invariably employ the bath in fever than to use an antipyretic drug as constantly, viz., because the bath strengthens, while the drug weakens, the patient's vitality; the one helping, the other hindering, the living organism in its efforts at elimination or vital house-cleaning.

No class of men are better able to appreciate the hindrances to the adoption of any radical innovation in medical practice than the present stanch advocates of the Brand bath in typhoid fever, and I trust that these, at least, will grant sympathetic attention to the writer's earnest advocacy of even so radical a prescription as that of the fasting cure for fevers, and other appropriate cases, to be as rigidly enforced as the bath itself, to say the least. The fasting cure, no less than the bath method, outranks in the matter of age all the drugs at present employed in the treatment of disease. and I feel sure that the two will survive them all.

Moderate feeding does not answer the full purpose. though of course less harmful than constant slopping. The fever patient's comfort is promoted in every instance by absolute fasting during the first few days, fresh water meeting best every craving of the stomach, and hourly half-teacupfuls of hot water supplying every require-

ment of the circulation, and if this plan be pursued faithfully but few baths will be needed; whereas, on the stuffing plan, the inevitable indigestion promotes the disease and renders necessary a great many baths. Indeed, after an experience in private practice of many scores of fasts, from two days' to two weeks' duration, I have come to feel almost complete relief from anxiety as to the outcome (in all these acute sicknesses which we all recognize as critical, yet possibly curable) as soon as my patient stops eating. I do not mean by this the mere skipping of a meal or two when nausea or lack of appetite causes the patient to dread the ingestion of food, although even this is a relief to the system, but I mean the total discontinuance of feeding until the purpose in view has been accomplished, viz., the practical abortion of the disease. This may mean a rest of the stomach for thirty six hours, or possibly several times as long, according to the early or tardy beginning of the fast, or the malignancy of the original disease.

The conclusions of Dr. Anton Gluzinski, of Cracow, after extended experimentation, seem to me worthy of very careful consideration in this connection. He says: "1. During the whole course of the fever (except in the convalescent stage of typhoid fever) the gastric juice contains no hydrochloric acid. 2. The gastric juice digests neither in the organism—since it contains no peptones—nor outside the organism. 3. With the disappearance of the fever, or somewhat later, the gastric juice becomes capable of digestion, both within and outside the organism."

This, as I contend, is the first moment in acute febrile disease where anything but harm can result from feeding. This opinion is based, not simply upon theoretical grounds—though it would indeed seem a most natural conclusion that undigested and unassimilated, and therefore fermenting, food must constitute a poisonous nuisance; but upon the results of the careful study of many victims of the feeding plan, as well as, in my own practice, my experience with a large number of persons who live to thank me for what antagonistic onlookers choose to term my "starvation" treatment.

It is my firm conviction that every case of perforation of the bowels, and, indeed, every long drawn-out sickness in typhoid fever, is a protest against the usual method of feeding and drugging; while every recovery serves only to illustrate the marvellous powers of the living organism to contend with disease-producing influences—a triumph of nature over bad living-habits and mistaken medical treatment. My own invariable practice is to withhold food until my patient is convalescent and unmistakably hungry, the test of hunger being a piece of stale Graham bread "dry on the tongue." At the right time this is delicious to the patient, and as useful as agreeable. Then, from day to day, careful increase, keeping rather hungry till all anxiety is past.

Under this plan we know practically nothing about relapses or any serious set-backs. Once on the mend progress toward restoration is sure and steady. For a time this "diet" of fresh air, soft water—nothing is more essential than that the water be soft—and the waste and effete matters of the body, "agrees" with the patient absolutely, and any sort of bathing demanded may be given at any moment without the least fear of provoking an attack of indigestion. In health we all eat too much, and one of the brightest physicians the world has ever known once remarked that if everybody knew enough to stop eating when they began to feel ill, one-half of all the doctors would be driven out of business.

In the matter of citing cases from my own record-books, as to the value of fasting in sickness, I am embarrassed with the wealth of such literature, and I hardly know where to begin. My own family furnishes a complete refutation of the charge that "doctors never take their own medicine," for this remedy is the one specific upon which we all chiefly rely. It is always exhibited so early in the case that it is commonly a question of a meal or two skipped; but in a very severe attack of "summer diarrhœa" that struck my little two year old son last August, the patient took nothing but water for about sixty hours. In a previous attack he got out of it very nicely with a thirty-six hours' rest from feeding. His little sister, during her three and a half years in a world where she has had "enough to eat," has had several fasts of twenty-four to forty-eight hours, and in none of them has the remedy disappointed me.

No simple diarrhœa can withstand the effects of a thirty-six hours' fast, while even moderate feeding, the patient being hungry or not, may provoke a constant flux for many days and produce, finally, an alarming, even fatal, disorder.

It should be remarked that the bowels closed by fasting will usually remain closed for some time after feeding is resumed, and no purge nor other means should be used; for there is a normal "constipation" after purging, whether the latter has resulted from food or physic. In a recent case of typhoid fever my patient had a perfectly natural movement on the fourteenth day, the first ten of which were fast days.

In the case of one young man, now enjoying perfect health, in three sicknesses during his boyhood—one of scarlet fever and two of rheumatic fever—there were fasts of eight to ten days in each case, and the entire treatment (including, of course, appropriate water-treatment) was entirely satisfactory to the lad and his parents, as well as to the doctor himself, except in so far as concerns the imminent danger of this young man's being henceforth practically his own physician, a state of affairs that might seem appalling to any young practitioner engaged in building up a strictly local practice!

Neither of the two "runs" of rheumatic fever above referred to were attended by serious pain such as always attends such attacks under the prevailing treatment. Fasting, hot-water drinking, and moderate cooling of the affected joints brought him shortly to a state in which he hardly lost any sleep.

A cousin of the above, a lad, aged nineteen, was attacked in April of the year 1893 with jaundice of the worst type, and enjoyed a fast of eight days, the first two being self-imposed (before I was called), from his familiarity with his cousin's experience in scavenging on his own body in sickness. Result, rapid recovery with no sequelæ.

The aged grandmother of these lads was attacked with a critical sickness—excessive vomiting, excruciating pain in stomach and liver. The fast in her case was of ten days' duration, and although her extreme age (seventy-four), her general ill-condition—very feeble, very stout (near two hundred pounds, at about five feet in height)—and the severity of the attack, would to most medical men of experience, I feel sure, have made the prognosis extremely dubious at the start, she was shortly convalescent and went on to complete recovery without a break, reaching finally a higher condition of health than she had previously enjoyed. There is not a trace of doubt in my mind but that any kind of feeding during the first few days of that illness would have been fatal to her chances of recovery. Even the employment of so-called nutritive enemata would have endangered her life, in my opinion.

In this case, as in every other case of fasting, the patient, while of course being allowed fresh water as desired, was required to take every hour or half-hour (according to complexion of the urine) a small half-teacupful of hot water (with placebo) throughout the daytime, when awake. It is essential that the fluidity of the blood be maintained, and there is only one substance that can accomplish this, viz., soft water.

The writer strongly desires to impress upon the minds of his readers the fact that, with the element of fear removed, death by starvation, with sick or well persons, is a very slow process, and that, therefore, no shade of anxiety need be felt by the physician in ordering any reasonable rest for the stomach. Not only have I personally superintended many scores of fasts for curative

purposes, with never an "accident," but I am in correspondence with several thoroughly trustworthy physicians who hold the same views from personal experience, and I have taken great pains to verify the truth as to quite a large number of reported fasts, accounts of which have from time to time appeared in the newspapers, of professional fasters, cranks, insane persons, and sick persons who had become tired of living in pain and have ended their own lives, or tried to, by voluntary starvation.

The fasts of Tanner (forty days), John Griscomb (forty five days, in Chicago), Succi, the Italian (forty-five days), and others of this class are well known to all the world, though the real value and significance of these tests seem to be comprehended by few even in the profession. These were robust men who had the courage of their knowledge, and I shall never forget the glow of satisfaction with which I read the Paris cablegram of the lamented J. Marion Sims to Dr. Tanner, at the time of the celebrated New York fast, the concluding sentences being as follows:

"Your experiment watched here with great interest by scientists, ridiculed only by fools. Hot weather is against you. Courage, brave fellow, hold on. Wish you success.—J. Marion Sims."

I will mention the case of one poor bedridden woman, already considerably wasted by disease and forced feeding, who in her despondency wished to die, and only succeeded after fifty-five days of abstinence from all food save water.

In 1882 I reported for the *Boston Journal of Chemistry* the case of an Irishman, aged seventy, who had been declining with consumption for three years, coughing, raising a great deal, often choking with phlegm, in spite of no appetite compelled to eat because no one interested in the case was wise enough to give his stomach a bit of rest, until finally he got angry with his disease, his nurse, and the doctor, and swore that he would never swallow another mouthful till he got hungry and could take food without hurting him. He fasted absolutely for forty-three days, when, his cough having ceased and his appetite restored, he expressed a desire for food. He began eating moderately of Graham bread and fruit. He soon began to gain a little in strength, and within four months was up about the house and grounds, shovelling snow, lugging in coal, visiting his neighbors, and I received a copy of the local paper containing an editorial notice of "Terence Connolly's remarkable cure of consumption from fasting." I corresponded with Mr. Connolly's brother in-law for several months from the expiration of the fast, advising as to the diet during convalescence, and until his health was fully restored, and his weight, which during the three years had fallen from about two hundred pounds to near one hundred pounds, and during the fast some twenty-five pounds more, brought to about one hundred and fifty pounds.

As for minor cases of fasting I will only remark that I am constantly directing stomach rests of a day or two for even the leanest persons when nausea, or lack of appetite, or other indications, point to the need of it. I will mention a few cases of very stout persons who have found great help from short fasts.

Mrs. R——, aged seventy-one, height five feet three inches, weight two hundred and four pounds, came to my office in a state threatening pneumonia. I directed her to return at once to her home, take a small half teacupful of hot water (in which was to be put my favorite placebo) every hour, fasting, during the balance of the day and the day following, till she should again, if able, present herself at my office, which she did in just twenty-four hours. She could now breathe with entire ease, and was delighted with the change, naturally. She weighed on my scales four pounds less than on the previous day. I placed a heavy cold compress over her chest on the first day named, directing her to freshen it on arriving home, and every few minutes during the balance of the day, in bed, or until fully relieved from the terrible pressure at the lungs. She had something like an hour of this active in-and-in cooling (compress wrung tightly from ice-water every two or three minutes), obtained satisfactory relief, and rested well that night. Next day, as stated, she called again, having walked over a mile with greater ease, she declared, than the single block from the street-car the day before.

A popular young physician consulted me for advice as to reducing his excessive weight. On one of his visits he was in a very serious bilious state, and for this I urged him to fast for thirty-six hours at least, with free hot water drinking (according to special directions), and I remarked quite seriously that if he made it a full week he would be the greater gainer thereby, little thinking that he would go the full limit. This was on July 7, 1890. On the 15th he again presented himself, remarking that he had just taken a light breakfast, the first morsel of food during the eight days. He now weighed three hundred and thirty-five pounds against the last weighing of three hundred and forty-nine and one-half pounds, a reduction of fourteen and one-half pounds, and he assured me that after the first two days he felt no inconvenience from abstinence, and that in no week for years had he attended to his very exacting practice so easily and with so nimble a step as during the week just passed. He was wonderfully improved in appearance, and was highly pleased with his improved condition.

Was this man starved during his week on a water-diet? Was he not fed, and better fed, than if anything had been added to the water, air, and foul matters, which constituted his evidently ample regimen?

Mrs. B——, aged forty, weight, July 24th, two hundred and twenty-one pounds, including a regain of five pounds from "visiting" friends and non-attention to diet. She felt, as she expressed it, "all bloated up," the garments recently taken in were again too tight. She was sent home with my "favorite prescription," to be taken for at least thirty six hours. Four days later, at about the same hour, she again stepped on my scales, having fasted the entire ninety-six hours, "because," she said, she "was feeling so much better," and her weight proved to be just ten pounds less than before. She had walked with ease nearly five miles to my office, and said she "felt like a new woman."

The physician who practises this method of "feeding" in appropriate cases will do well to be on his guard against surreptitious feeding, to which there is a strong tendency with most patients, encouraged by friends and attendants (victims, all, of false views, for which physicians must themselves be held responsible). The patient is not hungry, but there is a "gone" feeling, she gets impatient, "so long since I've had anything in my stomach," "so empty," etc. She is doing finely; only comfortably sick; temperature keeping down satisfactorily; strength increasing every day; but that does not suffice. She insists upon having a little gruel or some other slop, or perhaps takes a little "tea and toast" on the quiet. The physician, knowing that his patient, who has been mending every day, should be a little better this morning, finds her in fact restless, perhaps in pain, the temperature 102° F or more, instead of 100° or 101° F., as on the previous day, and he learns that she has been vomiting during the night! In fact, she has just the sort of set back, more or less serious, that is the common lot of all fed patients in similar cases, because she has violated orders and has been fed.

Sometimes, by no means always, the patient gets the needed lesson from the first punishment for disobedience, confesses, sticks to the regimen, and has no more "relapses." But, whether by the doctor's direction or the patient's own fault, every "cold" (a stupid misnomer, by the way), or simple fever, is likely to "run into typhoid," on the common plan of feeding, appetite or no appetite, regardless of the question of digestion and assimilation.

To the writer's mind the most pathetic thing, next to that of a deserving person's starving to death for want of food, possible to imagine, is for such a person to be

stuffed to death. Indeed the latter is by far the most painful method of the two, as it is the more frequent in every civilized community. It is both the kindest and the cruelest phase of "kicking a fellow when he's down." The motive makes it kind, while the results are so painful that the most inhuman person might well be content to witness the death-struggle, long drawn out, of an enemy dying from constant feeding. The most incorrigible hater of the Union cause during our civil war might well, if he could have comprehended the matter in all its bearings, have wished for Lincoln the prolonged and horrible death of Garfield, concerning whose taking off one of the most useful physicians in all England, as well as one of the noblest of men, the late Professor John Kirk, of Edinburgh, said at the time: "The most flagrant illustration of the abandonment of common sense and the following of absurdity is now being given in the case of the President of the United States of America. His feeding is perfectly monstrous, and shows that at least in high quarters ignorance and noise have all but supreme sway for the time. As it was in the case of Lord Beaconsfield, it is in this case—How much can he be got to swallow? It does not seem to be imagined that digestion, and, still more, assimilation, are more important than swallowing! But surely men need not be fools? They are not shut up by fate so that they shall think only transparent nonsense. Only just let in a very little of the most humble light, and surely you will see that assimilation—that is, the changing of food into healthy flesh and bone and nerve—is more essential to cure than swallowing the least adaptable substances without regard to such assimilation.

It does not require the wisdom of a sage to see that feeding, on the one hand, so as to load the system with inassimilable substances, and draining off pus, on the other hand, is the sure way to finish a patient's career."

Herein, I believe, is the true explanation of the old disease, under the new name, "blood poisoning," toxæmia—the sepsis—of which the freshest medical student now speaks as flippantly as though it furnished the solution of many riddles, if not the one most important of all, in this connection, viz., that of the sepsis itself! Sepsis is defined as "putridity or putrefaction, decomposition, rot."

Fermenting food putrefying in the stomach and bowels—decomposing, rotting—with all the vile products thereof—what student, blessed with a reflective mind, requires more than the simple presentation of this matter in this connection to settle for him the question of blood-poisoning, to the exclusion of the theory of "germs," or the reabsorption of foul matters that are working their way to the outside world.

In conclusion, I will relate an incident that came under my observation a few years since, one of many similar cases that are constantly occurring, the case of a lad of thirteen, sick with typhoid fever, who, while in his right mind begged to be spared the excessive feeding with milk, beef-tea (practically identical with urine), brandy, etc., and in his delirium fought with desperation against the ingestion of food. The physician in charge, one of the foremost in Maine, and justly regarded as one of the most skilful surgeons in this country, remarked that the loss of two teeth was a most fortunate circumstance, and the parents of the poor boy felt thankful enough for it, for by having the little patient held—hand, foot, and head—the various slops could be easily turned down.

This patient lasted about three weeks from the beginning of the attack, which was mild enough to constitute a good case under water-treatment, and who shall say that he did not, in that brief time, exhibit enough vital force in contending with drugs, and food, which for want of digestion was worse than many drugs, to have made his recovery a matter of certainty could he have been allowed to follow his own inclination, even as to diet, and been given a few life-saving baths, with freedom from all poisonous drugs.

867 Boylston Street.

THE LOCAL TREATMENT OF CHRONIC COUGHS.[1]

By E B BAYLISS, M.D.,

Dayton, O.

Mr. President and Gentlemen: In presenting to your notice the subject of local treatment as applied to chronic coughs, I feel that my feet are treading on a portion of scientific ground which has not been sufficiently worked over; which is not understood as well as it might and should be, and one the cultivation of which will be sure to lead to the happiest results to our patients and then, of course, to ourselves.

I have given my paper the title it bears for the reason that, while I believe that some of my cases were tuberculous in character, still, not having had a microscopic test made, it is impossible for me to affirm that such is the fact, or to defend the position, were I certain enough of the correctness of the diagnosis made from symptoms only to advance it.

Of course, the cases with which my paper has to do can be subdivided into bronchitis, laryngitis, tracheitis, etc., but as cough is the leading symptom in them all, and the one that is the most troublesome, it is the one that we are most solicitous about treating—the one whose successful treatment is most gratifying to all concerned.

Not all, perhaps not the majority of coughs have their origin in the lungs, for many times, it must be remembered, cases of this kind that are chronic and most distressing have their seat in the upper air-passages, the lingual, faucial, and pharyngeal tonsils being often responsible. These coughs, too, are the most difficult ones to master, the ones most refractory under constitutional treatment.

The relation between cause and effect in these patients is not always clear, but it is certain that these throat troubles have often the same bearing on a cough that a sensitive turbinate has on an asthma; indeed, they may themselves be the starting point of this latter trouble.

Every one of us has had under his care at different times cases of chronic cough, many of them of long duration, some even which have persisted many years; the patient being credited with having a wonderful constitution, since he has been able to live so long with consumption. Some of these cases have even been known to spit blood, and many of them have, no doubt, been allowed to die, not from phthisis, but from atony of the lungs, if so it might be called, resulting from a lack of exercise of the lung-tissue.

It is not my purpose to propose the supplanting of constitutional means by local ones, but simply to try to show that in these local measures we have an efficient help to the general remedies, so long tried and often so signally successful.

First among the local measures should be placed forced inhalations, either of pure air, or air medicated by one of many good and meritorious drugs. This method of treatment has had more advocates among the laity, I believe, than among the profession, yet of late it is being more thought of, as witness a paper lately published in the *Medical News*, by Dr. Kuhs, of Chicago, on the "Topical Treatment of Bronchitis," though this article has reference more to acute than chronic forms; also a reprint of an article by Dr. Thompson, of Cincinnati, on "Gummata of the Lungs;" a short paper lately published in the Medical Record, entitled "The Tooth-pick in Respiratory Disease," and others bearing on this subject.

In my boyhood days a travelling preacher used occasionally to visit my father's house, who gave credit for his cure from consumption to the use of copious draughts of fresh morning air through a tin horn, many years before. The horn, he told me, was ordered by his physician, but whether for mental effect, of course, cannot be told. And whatever virtue there may be in a

[1] Read before the Montgomery County Medical Society, January 19, 1894

prominent "consumption cure" that is now being quacked through the country, will, in my opinion, be found to be largely due to the inhaler, which is the most prominent part of each outfit.

Two cases of mine may be of interest just at this point.

Case I.—George B——, aged thirty; shoemaker; treated about 1888. This man was sober and industrious; the father of two healthy children; an American by birth and ancestry. He had the ordinary symptoms of a beginning phthisis—cough, loss of flesh, night-sweats, hectic, and signs of consolidation in left apex. He was put on the approved general treatment, was advised to procure a "jack" and work standing up, and in addition was told to go to a neighboring hill every morning, walk to its summit, and take long, deep inhalations of air. The number of these inhalations was carefully prescribed. Six months of this treatment made a perfectly well man of him, at least for three years, after which I had no news of him.

With compressed air quicker results may be obtained, as is shown in the following case:

Case II.—J. S——, aged about thirty. This man is a saloon keeper and has been known as a consumptive for years, having had severe hemorrhages and all the other classical symptoms of that disease. In habits he is fairly regular. He was referred to me for treatment by Dr. Hooven last July, at which time his cough was very severe. He had chronic laryngitis, was expectorating more or less blood, and was unable to obtain necessary rest on account of evening chills and fever, together with morning cough. He was treated by applications to his vocal cords, cauterization of the lingual tonsil, and forced inhalations of creosote mixture. The improvement was rapid, with entire disappearance of all symptoms, so that he was free from his cough for the first time in ten years, gained twenty five pounds in weight, and retains all that he gained. It should be added, too, that after he finished taking what sirup of hypophosphites he had on hand he took no more constitutional treatment.

Other cases could be mentioned, among them one of tracheitis. In this case the relief was pronounced, but, as the patient went some distance from the city to teach school, I am unable to state whether or no it has remained permanent.

The explanation of the efficacy of this line of treatment is, I think, to be found in the exercise of the lung-tissue that it causes, and in the consequent increased flow of blood into these organs, which results in its more complete and thorough purifying. We all know about the tidal air, the supplemental air, and the residual air, and can very easily understand how an increased movement of all three must be beneficial in these cases. Though the medication is, no doubt, also helpful. Combined with the inhalations in many cases it has been found that cauterizations are of service.

As I remarked earlier in the paper, many times the cause of a cough is an enlargement of one of the tonsils. Although it cannot, of course, be held that enlarged tonsil always makes trouble of this kind—indeed, we know it does not—still, when it does, a judicious reduction of it by galvano-cautery will work wonders in the way of a cure. This I had the pleasure of seeing clearly shown in the case of a bright boy in the Brooklyn Nose and Throat Hospital, six cauterizations of the left faucial tonsil entirely curing an obstinate, rebellious cough of over a year's duration. It has also been shown to be of value in several cases lately under my care. Indeed, in one case, which is at this time remaining under observation, though not receiving active treatment, this method was almost totally relied on. This was also a referred case, and the result of treatment was one most pleasant, and of course very gratifying, to the patient and her friends.

Applications to the vocal cords and upper trachea seem to me to be of least importance, yet in cases where there is a thickening of the vocal cords with hyperæmia or ulceration, there can be no question of their usefulness as palliative, if not curative, agents. It should not be forgotten, too, that an enlarged palate may call for a cutting operation, as may enlarged faucial, or more likely, pharyngeal, tonsils.

In closing, it may be well to state that diagnosis is most important, especially when one is contemplating the use of the cautery, and in this diagnosis the ability to handle the laryngoscope is a prime necessity. While, as I said before, this line of treatment is intended to be used only as an adjuvant to constitutional measures, it is my opinion that a thorough investigation of its merits will well repay one for the time involved.

1535 East Fifth Street.

FRACTURE OF NECK OF FEMUR IN SENILITY.

By A. T. HUDSON, M.D.,

stockton, cal.

In the Medical Record of September 16, 1893, Dr. Allis remarks: "Fractures of the neck of the femur in the aged should be managed by treating the patient and not the fracture. Leave off apparatus, use sand-bags, do everything that will make the patient comfortable and prevent bed-sores."

Two unsightly deformities must inevitably result from Dr. Allis's non-treatment of the disabled leg. These are shortened limb and everted foot. These five cases which follow go to show that both the patient and fracture can be treated at the same time with success, and without detriment to the former.

This injury follows so slight an accident—a trip of foot and fall upon the floor—as to mislead the young surgeon. Then will follow a mistaken diagnosis and defective practice. This is exactly what did happen in the first case my brother, Dr. A. S. Hudson, met with. The error was not his, but it was made by the older physician who was called in consultation.

Twenty years ago this brother worked out a diagnosis of fracture of neck of femur by means of one symptom. It is as follows: A person in good health and over forty receives a fall. He is disabled and cannot get up without assistance. What does it mean? It means nothing less than a broken bone, and invariably a fractured femur at the neck.

Therefore, bear in mind this one symptom alone, *i.e.*, absolute disability after a fall is proof of a broken femur. This is independent of the four signs of the text-books.

Case I.—Mrs. J——, aged seventy-four, of small, spare figure, fell from a porch of two or three steps to the ground. Was unable to rise; was carried into the house. Proofs of fracture of left hip above the trochanter were apparent and conclusive. The simplest dressing was applied, viz., adhesive strips along the leg to the knee, by which to make extension with a weight over a pulley attached to the foot of the bed. Long bags of sawdust were placed against the limb and hip to keep the member in place and in position. At first the case was looked after day by day, and measured to see that there was no shortening or eversion. Time of treatment was eight weeks or more.

So perfect was this recovery that one could not tell from her walk which limb had been injured.

Case II.—Mrs. U——, a fleshy woman, aged seventy-two. Going out of the door she fell one or two steps to the ground. Finding herself helpless she was assisted into the house. Chloroform was given, and a diagnosis of fractured neck of the femur was made. Dressing was applied as in the preceding case. No splints or bandages were used except such of the latter as were necessary to hold the adhesive strips from creeping down. The seven-pound weight brought a sense of relief instead of being a burden. In due time the patient recovered without deformity or shortened limb.

A year or so after, Mrs. U—— got another fall and injured the same hip. At this period she had moved from town several miles into the country. This time she did

not appear wholly disabled, as she could bear most of her weight on the damaged leg. There was no shortening or eversion of foot. So the case was left in doubt, and no treatment adopted. But plain instruction was left to watch events, and if changes in the way of deformity occurred to let me know, so that the injury might receive proper attention. Nearly a year passed and no message came. But by accident the patient was seen and examined. The limb was found to be half an inch short and foot everted. This carelessness of the patient, with such a result, was by no means satisfactory to anybody. It was too late to remedy the condition.

Case III.—Mrs. S——, aged eighty-one; a large, fleshy person. Her foot caught in the tangled grass and falling to the hard ground she broke the right femur at the neck. In none of these examples was there any effort made to determine whether the injury was within or without the capsule. The same simple treatment was adopted by extension, weight and pulley, and the use of sawdust bags. [A pillow under the knee which puts the limb on an incline is restful and sometimes much needed.]

At the time of the accident this patient was suffering from a kidney trouble and rheumatism. Still she made a perfect recovery in every feature. Owing to the rheumatism, she said, the restored broken leg was the best of the two.

Case IV.—Mrs. F——, aged eighty two; had a heavy, fleshy figure. She stepped on a rolling stone and was thrown to the hard ground. This fall broke the right femur at the neck. Wholly disabled, she was helped into the house and to her bed.

The diagnosis was easy and without perplexity. The same dressing by weight, pulley extension, and sawdust bags was employed. In ten weeks she left her bed and walked about. Though this was the oldest of the five cases, and all women, she made a good recovery. There was no shortening of the limb and no deformity.

Case V.—Mrs. W——, aged sixty-six. Habit robust and fleshy. For twenty years she had been lame from an injured ankle, which had made the limb three-fourths of an inch short and somewhat stiffened. She tripped her foot in a floor rug, fell on the carpeted floor, and fractured the neck of the femur on the right side. Unable to rise she was assisted to her bed. Soon there followed the usual shortening of the injured member.

By slow and careful extension the leg was brought down to its normal position by weight and pulley, or, as Bryant calls it, "elastic pulley." The hip and leg were adjusted and supported by sawdust pillows, which afforded ample relief. No splints nor perineal band were used. But a most important and convenient fixture was supplied. That was a long piece of wood, three inches by two, extending from the head to the foot of the bed, and within her reach. On this level bar was a rope or hand-piece for the invalid to lay hold of in order to turn and raise herself, change position, and afford some exercise, without calling on others for assistance. This patient gained several pounds in weight during her nine weeks' confinement to bed.

In all the above cases elevation of the foot of the bed was sufficient to obtain counter-extension.

If in these injuries, after dressing is done, the injured limb has the same length and pose as its fellow, and the patient feels easy and comfortable, you may be sure that everything is right and the patient is safe to leave. But whenever there is pain or suffering of any kind, there is something wrong, and it must be looked after and the mischief corrected. To insure a perfect cure without fail, the case should be looked after every day or so, for a week, then every few days or weeks.

In view of the benefit to the sufferer these few cases convey, and in view of the fifty-two successful cases out of one hundred reported by Bryant, it seems to me the surgeon is remiss in his professional duty not to give the unfortunate the advantage of such measures. For those invalids are to go through the balance of their lives limping, and in more or less pain. Immunity from this perpetual pain alone is ample reason for justifying our assistance.

A NEW AND ORIGINAL METHOD OF CORRECTING THE "REVERSE" OF THE POSITIVE STATIC CHARGE; WITH FURTHER PRACTICAL SUGGESTIONS.

By S. H. MONELL, M.D.,

NEW YORK.

It is well known that the static electrical machine occasionally reverses the position of its positive pole. To prevent this occurrence Holtz introduced his ingenious diagonal conductor, a device which does not wholly remove the fault, though it greatly increases the stability of the electrical charge. When this occurrence takes place in practice it is usually accepted as being without a remedy, no matter how much it may inconvenience the physician. In my own past experience, when my machine has reversed, I have made fruitless inquiries of the manufacturing firms and of the various workmen who construct the Holtz apparatus, and have consulted every accessible authority on the subject of static electricity. I find no mention of any known way to restore the lost position of the positive charge, and am conclusively informed that no way exists. Owing to the situation of available space and the relation of certain office accessories, it is frequently a practical necessity to have the positive pole at a particular end of the machine, where the physician becomes accustomed to its use. This being my own case, a reversal of polarity operated as a decided hindrance, and I therefore investigated the conditions which appeared to influence the shifting charge, with the result that I have discovered a method, successful with me, which I desire to report so that it may be generally tested and serve others who are inconvenienced in the same manner. The method is as follows, viz.: Discharge the machine; place the sliding poles in proximity; strike a few sharp taps with a hammer on the outer end of the brass cross rod supporting the upper set of diagonal combs, and recharge the machine. The ornamental tip of the rod may be removed for this purpose. On a "good day for static" the process will not be so simple, as the charge seems then more tenacious. I have then been obliged to remove a door and tap the rod and diagonal conductor inside the case, and repeat the attempt a number of times with some degree of patience before success resulted. As a further aid the prime conductors may also be struck in the same manner if the result is not speedily attained.

If one attempt fails, try again. A machine is almost certain to be found reversed after any repairs have been made to it, and at such times a way to correct the trouble is of practical service. In my own hands I believe the method will repeat the desired result whenever occasion requires, as I have now a record of eight tests made on various days, and see no reason why it should hereafter fail. I have spoken above of "discharging" the Holtz machine. It is done in the following manner: Place the sliding poles about half an inch apart. Revolve the plates backward until only a residual charge is left, and draw this off with a grounded electrode. On a "good day" this may require opening one end of the machine, but may usually be accomplished with ease. When occurring by accident, this was formerly one of the bugbears of every static operator. The cat-skin excitor, which was far from a perfect reliance in recharging the Holtz machine, especially under unfavorable conditions, has, however, given place to a miniature Wimshurst charger now furnished by leading makers, and one great source of annoyance has disappeared. To lessen the liability to inopportune discharge when the machine is not in action, the poles of the prime conductors should be drawn wide apart and left so. Inasmuch as the pole of chief importance in the administration of static electricity is the pos-

itive, and as many physicians find it necessary to distinguish this pole from the negative without any familiar means of doing so. I will repeat here the two simplest methods that I am in the habit of using: Start the machine into action with the sliding poles in contact. Draw them apart until the brush discharge remains upon one pole only. This will be the positive. The brush, or broom, at this pole also possesses a short handle, similar to the short handle of a whisk-broom. This handle is a stream of continuous sparks, at the end of which the discharge bursts into the bluish luminosity called the "brush." The broom handle is lacking at the negative pole. This method is best applied in a somewhat darkened room, but as most physicians' office work is done in morning hours, I then adopt a method serving equally well in the brightest daylight. Starting the machine into action with the poles placed so that a bright stream of sparks—say two inches long—will be thrown between them, I intercept this stream with the head of an ordinary match. When the current is thus obstructed at its point of origin the stream will be dispersed. By slowly drawing the head of the match around the surface of the ball from which the discharge leaps into the air-space between the poles, the broken spark-stream may be attracted at will through a radius of perhaps half an inch. When the match is placed in contact with the opposite ball, and in the line of the sparks, no effect on the continuous volley is observed. Remembering that the current flow of frictional electricity is the same as the current flow from a chemical battery, *i.e.*, from + to —, it is clear that the pole to which the spark-flow comes in an undiverted stream is the negative, and the ball from which the flow is impeded, scattered, and broken by the obstructing match, is the positive. It may be mentioned in passing that this test is made without igniting the match or producing any "shock" or sensation in the operator's hand. It is done almost in an instant, and is as accurate as it is simple.

Another minor point which may interest a number of readers relates to the grounding of the inactive pole of the static machine and the electrode used in the treatment of a patient. If a water-pipe or gas-fixture is not handily situated, the unused pole may be satisfactorily grounded by running a chain or wire from it to the register of a furnace. This is much better than to simply drop the chain upon the floor. My excuse for presenting the above items of what may be considered merely technical information, is to be found in the meagreness of literature upon the subject, the largely increasing number of physicians who, while becoming interested in the operation of the static machine, may lack opportunity of fully familiarizing themselves with the minor details of its management, and the fact that personal experience has demonstrated both the practical value of what I here narrate, and the dearth of similar information in medical writings.

665 Lexington Avenue.

The Strongest Man at Harvard.—A new strength record has been made at the Hemenway gymnasium, Harvard, by Edward Klein, '95, of Deerfield, Mass. The best previous record up to this time stood to the credit of S. L. Foster, '85, in 1884. His total strength was 1,348.8 points. Klein's total of 1,445.6 points is made up as follows: Strength of lungs, 23; strength of back, 340; strength of legs, 740; strength of upper arms, 201.6; strength of right forearm, 78; strength of left forearm, 63. Klein's record is likely to stand for some time, unless he himself improves upon it. His total last year was 1015.2. By Dr. Sargent's system of measurements, the total is determined as indicated above. The strength of the upper arms is calculated by adding the number of times the man pushes himself up on the parallel bars, or, in other words, the number of times he dips to the number of times he pulls himself up on suspended rings, and by multiplying this sum into one-tenth of the weight.

Clinical Department.

THE ACTION OF ELECTRICITY ON THE PNEUMOGASTRIC—IS IT OF VALUE IN CHLOROFORM NARCOSIS?

By A. D. ROCKWELL, M.D.,

NEW YORK.

On December 28, 1893, a child, aged six, was brought to my office with a large nævus materni or erectile tumor upon the cheek. She was chloroformed and needles introduced into the enlargement preparatory to the electrolytic action of the current, when suddenly the respiration ceased, the pulse became imperceptible, and the only evidences of life were very faint and convulsive heart-beats. A faradic apparatus was at hand and one pole was immediately placed at the junction of the clavicle and the outer border of the sterno-cleido mastoid muscle, and a vigorous current applied. Evidences of returning vitality were seen almost immediately, and within a few moments the heart was again beating regularly. Did the electricity accomplish the good in this case, or, as some might claim, did the heart, unaided, resume its normal action? The question as to the influence of electricity on the heart through its action on the pneumogastric, is certainly a very interesting and a very important one. It has been claimed that in chloroform narcosis electricity will do more harm than good, since its tendency is to stimulate still further the inhibitory function of the vagus. My experience, however, is that ordinary external applications affect the inhibitory fibres of the vagus that go to the heart in no such degree as they affect the accelerating fibres which in great measure constitute the branches that supply the respiratory organs. The very remarkable effects of the faradic current in keeping up the respiration in cases of opium-poisoning are known to all. In one case of this kind that I saw, where the current was continuously employed for six or eight hours, the respiration would sink to two or three a minute, and the heart-beat manifestly weakened whenever the action of the current was interrupted.

Immediately on resuming the current the respiration would increase to eight per minute, and as the effects of the opium gradually wore away, the frequency of the respiratory act increased.

Now, in this case and in others of a like character that have fallen under my observation, it is fair to conclude that the current affected the accelerating fibres of the vagus controlling respiration, and not to any considerable extent the inhibitory fibres controlling the action of the heart. In chloroform-poisoning, of course, a different condition of things prevails. The heart is under sedation, and any increase of the inhibitory effects of the pneumogastric might be dangerous. Fortunately there is little danger of this in the use of the induced current, at least in ordinary percutaneous applications.

According to Von Ziemssen, who made many carefully conducted experiments by means of cardiographic tracings, induced currents have absolutely no influence on the frequency or force of the cardiac contractions, and from that fact the erroneous conclusion has been drawn that induction currents were valueless in threatening death from heart-failure. The facts are that electricity does good in increasing respiratory activity, the strength of current necessary for this purpose being insufficient to materially interfere with the movements of the heart, through its action on the inhibitory fibres of the pneumogastric that control it. Dr. George F. Shrady reports the case of a boy where death was imminent after the administration of chloroform. Respiration ceased and the pulse could not be felt, but through prolonged artificial respiration the life of the patient was saved. This confirms the report of the Hyderabad Commission, "that it is of primary importance to keep track of the respiration in administering chloroform: if this is kept up the heart will give no trouble."

A CASE OF ROUND-CELLED SARCOMA OF THE OVARY.[1]

By G. H. MALLETT, M.D.,

HOUSE SURGEON WOMAN'S HOSPITAL IN THE STATE OF NEW YORK.

SOLID tumors of the ovaries are much rarer than cystomata. The great majority of authors place their frequency at five per cent. of all cases of ovarian growths submitted to operation, while of this number about one per cent. are sarcomata.

Sutton thinks that many of the specimens found in museums labelled fibromata of ovaries are in reality fibrosarcomata. Of the two varieties of sarcoma the spindle-celled occurs more frequently than the round-celled.

Solid growths of the ovary are more often bilateral than cystomata. This is particularly true of carcinomata and sarcomata. Sarcomata of the ovary differ from sarcomata generally in that they frequently occur primarily in both ovaries, and in the circumstance that masses of tissue which under the microscope are indistinguishable from sarcomatous tissue occur not infrequently in association with ovarian dermoids. They are usually moderate in size, seldom larger than a cocoa-nut. They are generally much less irregular than are cystomata and have fewer adhesions.

That they have few adhesions is thought to depend upon their smaller size and upon the frequency of ascetic accumulations. The surface of sarcomata is smooth as a rule, and of whitish or pinkish-white color. The consistency of the spindle-celled variety is quite firm, while that of the round-celled is soft and brain-like.

A comparatively large proportion of cases occur in early life. The three cases that have come under my observation were in young unmarried women.

Among the 37 cases reported by Olshausen 5 were under twenty years, 9 between twenty and thirty years, and 18 between thirty and forty years, and 4 between fifty-eight and sixty-seven years. The course and duration of the disease varies considerably; some terminate in a few months, while others have had a duration of nine years. The diagnosis is very difficult to make, as the symptoms arise from the ascites and from pressure.

The following case of round celled sarcoma I report by the courtesy of Dr. Clement Cleveland:

Miss F. H——, aged twenty, admitted to service of Dr. Cleveland, May 16, 1893. First menstruated at thirteen years. Type, 28 days. Scanty flow for one day with pain. Last menstruated, May 7th. Three months before admission she noticed an increase in the size of her waist. Two weeks previous to entrance to hospital she felt a sharp pain in right iliac region, for which she consulted a physician. A tumor was then discovered. Since then she has been able to appreciate it herself.

Physical Examination: Patient well nourished, slightly anæmic. Large tumor felt through abdominal wall occupying right side of abdomen, filling the pelvis and extending up to the liver. By vagina, mass felt to right side and back of uterus. Uterus normal size; position forward and to left; cervix normal. Upon admission patient had temperature of 100° F.; pulse, 94. This continued until May 21st, when the temperature rose to $104\frac{5}{10}$° F., where it remained until the following day, when she was operated upon.

Operation, May 22d: A median incision was made which extended from symphysis to about two inches above the umbilicus. A large, solid tumor presented immediately below peritoneum. It was so friable that it was removed with difficulty; no adhesions. The pedicle was so large that it was found necessary to quiet it with the ligature. The stump was cauterized and a glass tube inserted into the cul-de sac. Abdominal wound stitched with silkworm-gut and dressed with wet bichloride gauze. Patient removed from operating-room in good condition. At time of operation temperature was $104\frac{5}{10}$° F.; five hours later it reached 106° F.; pulse, 124; respiration, 32. From that time it went steadily down. With the exception of a sinus which followed the use of the drainage tube, her recovery up to the present time seems to be complete.

Pathological Report.—*Macroscopic Examination.*—Bilobed lobulated mass of an oval shape, measuring 22 ctm. in length, 16 ctm. in width, and 10 ctm. in thickness. *Microscopic Examination.*—Small, round-celled sarcoma.—G. F. Freeborn, Pathologist.

The points of interest in this case seem to be as follows: The excellent general condition of the patient, she having suffered no emaciation and was not cachectic. She suffered no inconvenience from the mass until two weeks before admission to the hospital. The high temperature and apparently necrotic condition of tumor. There was no ascites. The disease was unilateral.

COMPOUND COMMINUTED FRACTURE OF THE SKULL, WITH REPORT OF A CASE.[1]

By WILLIAM H. SHIPPS, M.D.,

BORDENTOWN, N. J.

INJURIES of the cranium may be classed under five heads, viz.:

1. Simple fracture without depression.
2. Simple fracture with depression, but without symptoms of compression.
3. Simple fracture with depression and symptoms of compression.
4. Compound fracture with or without depression.
5. Compound fracture with or without symptoms of compression.

As subdivisions of these, we have what is rarely met with—fracture of either the internal or external table alone. Such, in brief, is the classification of Gross, accepted with slight modifications by most surgeons to day.

While it would doubtless be interesting and instructive to take up in detail the study of the various forms of cranial injuries and note their distinctive features, both as regards the character of the wound and the accompanying symptoms, our time will allow but a hurried glance at a single subdivision of the subject, namely, compound fracture of the skull with and without depression of bone.

Compound fracture of the skull is always a grave injury; it is rendered doubly so when there is associated marked depression of bone, together with the characteristic signs of compression—coma, convulsions, and paralysis. Compound fracture of the skull as occurring in early childhood is a rare accident; thus of 504 cases of fracture treated in the Children's Hospital, Philadelphia, but 6, or a little over one per cent., were of the cranium. Beck's record of 204 cases of fracture in the Children's Hospital at Basle shows but 2.8 per cent. to be of the skull.

Compound fracture of the skull without depression of bone may or may not be accompanied by a train of symptoms demanding operative interference. If after such an injury the patient shows no evidence of cerebral complications, such as coma, paralysis, or convulsions, no immediate operation is called for. This is in opposition to the teachings of the older writers, who advised operation in all cases of compound fracture, whether accompanied by evidence of compression or not. Even when slight depression exists in compound fractures it is an open question whether trephining should be resorted to in the absence of positive evidence of compression. Ashhurst,[2] in a most excellent article on cranial fractures, says, "The rule which I adopt in depressed fractures is that when the fracture is impacted, even if compound, there is no occasion for trephining as a primary operation. If the depression is only of such extent that the outer table of the depressed fragment has not been forced below the inner table of the surrounding skull, the depression is

[1] Read before the Burlington County Medical Society, January 16, 1894.

[2] International Clinics, 1892.

necessarily slight. The brain cannot be much pressed upon, for there is normally a certain space between the brain and the skull filled with the subarachnoid fluid. There can be no direct pressure upon the brain by a depression of this moderate character."

When it comes to compound fracture with marked depression associated with unmistakable signs of compression, the duty of the surgeon is clear; in fact operation with elevation of the depressed fragments is the only alternative. Sometimes this can only be accomplished by the trephine; in other cases simply removing the loosened fragments of bone allows of the introduction of the elevator and restoration of the depressed bone. Neglect to operate under such circumstances places the patient's life in jeopardy, and not unfrequently leaves him the victim of epileptic attacks the balance of his days. In proof of this, allow me to cite one of two cases that came under my notice during the past six months.

Nellie B——, a young woman, nineteen years of age, has been the subject of epileptic seizures since early childhood. At four years of age she received a violent blow upon the head from a brick, fracturing the skull; the wound was dressed by the family physician and in due time healed. Soon afterward, however, she was seized with convulsions, which have continued at frequent intervals ever since. My attention was directed to the case by a relative who was then under my care, with the request that I prescribe for her ailment. On examining the head there was noticed a marked depression of the anterior portion of the left parietal bone, fully two inches in length, and a half inch in depth. At the time of the accident the depressed fragments of bone were evidently undisturbed, at any rate restoration was but imperfectly accomplished, with the result as I have pictured.

The case I am about to describe, and which forms the text for the preceding remarks, presents the following history:

On Christmas day, I was summoned to go some distance into the country to attend a little patient said to have received a severe injury to the head. It seems the little fellow, with one or two playmates, was engaged in the dangerous pastime of placing nails upon the railroad track in front of his house, with the idea of having them flattened out by the approaching train, then in sight. As the train, running at the rate of twelve or fifteen miles an hour, passed by, the boy crouched to the ground to guard against injury. Unfortunately he sprang to his feet too soon, for the next instant the step of the caboose struck him squarely upon the top of the head, knocking him senseless. He was picked up, carried into the house and placed upon a settee, where I found him on my arrival several hours later. A neighboring physician previously summoned was washing the blood from the child's face and head—there had been considerable hemorrhage—the patient was in a semi-comatose condition; this, with extreme pallor of the face, cold extremities, frequent and feeble pulse, dilated pupils, and paralysis of the right upper extremity, indicated some grave injury to the central nervous system. Examination revealed an open wound three quarters of an inch in length, situated about the middle of the left parietal region; the wound was filled with clotted blood, which was removed. Introducing the index finger, I found the skull fractured, with decided depression of the fragments. I at once advised an operation, which was acquiesced in. The patient was quickly put under an anæsthetic and placed upon a table, the scalp being thoroughly cleaned and shaved, the wound was freely enlarged and the fracture brought to view. In outline it was almost ovoidal, two and one-half inches in length, and three-fourths of an inch in width, and split up into three fragments, the smallest of which, triangular in shape, measured three-fourths of an inch at its widest part, and one inch from centre of base to apex, its apex tilted upward, its base pressed downward upon the brain [specimen exhibited]. Without much difficulty it was removed by the forceps, leaving an opening corresponding in size and shape to the portion extracted. The brain, now plainly visible, was found intact. With an elevator the depressed fragments were brought into position, loose spiculæ of bone removed, the wound cleansed with bichloride solution, and the edges of the scalp approximated by silk sutures. Contrary to the rule adopted by many, no drainage-tube was inserted, a small opening being left at the most dependent portion of the incision for drainage if necessary. Iodoform was freely dusted over the surface, carbolized gauze and absorbent cotton applied, and the whole firmly held in position by a recurrent bandage. My reasons for not using a drainage-tube were, that the healing process is delayed thereby, there was no injury to the brain substance, and, finally, experience shows that cases of scalp injury unaccompanied by serious contusion of the muscular substance, heal with little or no suppuration, provided due attention is paid to modern antiseptic methods. The following day I again saw the patient and found him resting comfortably, intelligence perfect, movements of the arm normal, and his general condition all that could be desired.

No nourishment whatever was given for the first twenty four hours; for the following three or four days liquids only were allowed, afterward a gradual return to his customary diet was permitted. On January 4th, the date of my last visit, and ten days after receipt of injury, the child was sitting up out of bed. On removing the dressings the wound was found healed its entire extent. Not an untoward symptom followed the operation. The case is of interest from the facts, 1. That compound fractures of the skull occurring as a result of force directly applied by a moving body like a train of cars, usually terminate fatally. 2. The rarity of the injury in early childhood. 3. The prompt disappearance of all unfavorable symptoms after operation. 4. The rapid and satisfactory recovery of the patient.

Progress of Medical Science.

The Pathology of Bronchitis.—The relation of bacteria to bronchitis has been elucidated by two recent writers, Marfan and Claisse. A large division of bronchitis comprehends specific infectious forms; another division, the non specific bronchitis. Every bronchitis, however, according to Marfan, is infectious. The specific forms attend measles, whooping-cough, small-pox, influenza, etc., and are dependent on the microbe that causes the disease. These forms are "exogenous" or "hæmatogenous;" the germ is brought by the air or by the blood. Most bronchites are exogenous, but those of small-pox, glanders, malaria, and secondary syphilis are hæmatogenous. The non specific infectious bronchites constitute a large and important class. Under this head are included common bronchitis (*a frigore*), the bronchitis that attends chronic naso-pharyngeal affections, chronic affections of the lungs and pleura, hay fever, gout, heart disease, Bright's disease, etc. To this division is assigned the bronchitis which is present as a complication in all adynamic and cachectic states, as in infectious endocarditis, diphtheria, typhoid fever, diabetes, etc. Bronchitis is the rule in typhoid fever, but it is only a secondary element, and is not due to the presence in the bronchi of Eberth's bacillus.

Marfan's explanation of bronchitis from "catching cold" is substantially as follows: Acute bronchitis is sometimes occasioned by the respiration of a cold atmosphere which penetrates the bronchi suddenly and violently. But it is not by the direct contact of cold air with the mucous membrane of the respiratory passages that bronchitis is ordinarily produced. It is generally by a sudden chilling of the cutaneous surface, and especially when the body has been overheated by prolonged exercise and is perspiring. Marfan remarks that some persons have a susceptibility to cold when this is limited to certain anatomical regions; for instance, one will have

bronchitis if the feet are allowed to become cold, another, if he remains an instant with arms or chest bare, etc. Moreover, cold and damp climates and chilly seasons have a great influence on the development of bronchitis *a frigore*. The same may be said respecting sudden changes of weather. Infants, old people, and feeble cachectic subjects are particularly susceptible, for reasons which are sufficiently obvious. But how does a chill act in provoking an inflammation of a mucosa? The old medical writers supposed that the sweat-glands were closed by the cold and that the excrementitious matters of perspiration were retained in the blood. Hence, a general toxæmia, with inflammatory manifestations in parts of least resistance. This notion is now abandoned. Experiments have shown that in animals which are overheated, there is considerable dilatation of the cutaneous vessels; the blood circulates there with force and abundance. If now a sudden chilling is brought about, the blood which distends the peripheral vascular network is cooled in mass and by repercussion cools the organism. This sudden loss of heat causes profound disturbances in the internal organs. Severe congestions result. But the experimentation stops here, and cannot explain why the fall of the internal temperature engenders bronchitis. The bacteriological study of the sputa completes the data furnished by experimentation. Note in the first place, that the upper air-passages and bronchi contain microbes independently of any pathological state. Among these the four following species have been observed which have pathogenic properties: the staphylococcus pyogenes (aureus et albus), the streptococcus pyogenes, the pneumococcus, the pneumo-bacillus of Friedländer. Let now a bronchitis of whatever nature supervene, and it will be seen that these microbes are more abundant in the sputa; new species appear; proteï which are pathogenic and even pyogenic when inoculated in animals; two saprogenous microbes, the one resembling Eberth's bacillus, the other, the bacterium coli commune. Cornil and Babes remark that these microbes are found in all the bronchites; in bronchitis *a frigore*, in influenza, tuberculosis, morbillous bronchitis, etc. Marfan, besides those above mentioned, has also found the pneumococcus in the exudation of almost all the bronchites which he has examined. Pausini declares that the streptococci are the only micro organisms met with constantly in the sputa, both in bronchitis and in health. He describes eight different species of these streptococci, several species of fungi, twenty-one species of bacilli, ten species of micrococci. Frick has studied the chromogenic bacteria which give to sputa their green color. Marfan, in summing up these bacteriological results, asks what conclusion can be drawn therefrom concerning bronchitis *a frigore?* Although the direct demonstration has not been made, it is difficult not to think that all these microbes have a real pathogenic influence. Whether they live normally in the respiratory passages, or whether they come from the atmosphere, it must be admitted that the cold favors their fixation and their pullulation in the mucosa of the bronchi. The solution of the problem then consists in knowing why the perturbation caused in the organism by the cold favors this development of micro organisms. In the normal state the system defends itself against microbes by the bactericidal properties of the serum and the phagocytic properties of the anatomical elements. These two sets of properties are in part dependent on the nervous system. It is very likely that the profound perturbation produced by the cold on the internal calorification, brings about a disorder of the vaso-motor innervation which causes congestion and places the organism in a state of lessened resistance, and just in those localities (respiratory passages, skin, intestine) where microbes are normally present we see inflammations set in of microbic origin which are properly designated infectious, non-specific. It is easy to conceive that a first attack of bronchitis diminishes the power of defence of the bronchi and leaves behind certain microbes that are more virulent, and this naturally favors recurrences. What is said of bronchitis *a frigore* is just as applicable to coryza from cold, and when the two coexist the explanation may be as follows: Either the cold acting in the same manner on the nasal and bronchial mucosa, favors the microbian invasion, simultaneous or successive, of the two mucosæ; or the coryza alone is produced by the cold, and the microbes having acquired their virulence in the nasal fossæ, invade later, by simple propagation, the tracheo-bronchial mucosa. There is nothing at the present time that indicates which view of this pathogency is the more correct. Certain it is, however, that bronchitis *a frigore* is generally preceded by a coryza; and it is regarded, from a clinical point of view, a descending bronchitis

The article of Claisse adds to the above statement the notion of intoxications by microbe secretions. The presence of the microbe in the bronchi manifests itself by local effects on the tubes and by general toxic effects. The local effects are expressive of the secretory reaction of the bronchial tree; this, in certain conditions, may lead to a more or less extensive obliteration of the air-passages and give extreme gravity to the prognosis. But the bronchial secretions may also have a marked toxic influence; this is a pathogenic factor that has been too much overlooked. The toxæmia explains the general phenomena, the temperature, and, to some extent, the dyspnœa. Claisse has made some interesting experiments to determine the nature and quality of these toxines, and has worked out the bacteriological problem with considerable success; but the details of these researches may be considered later.—*Boston Med. and Surg. Journal.*

The Value of Creosote in Gastric Fermentation.—Creosote has been so largely used within the last few years in the treatment of bronchial or general pulmonary disease, that many of us have forgotten the valuable results to be obtained by its employment in the treatment of gastro intestinal troubles associated with fermentation. As is well known, the name of the substance is derived from the fact that it was found to prevent decomposition of nitrogenous matter, and that it therefore acted as a distinct antiseptic. There are two classes of cases of indigestion or disorder in the alimentary canal in which creosote is of great value. Aside from those instances of persistent vomiting, where by its local action it often renders us great service, it is also useful in those cases of fermentation or chronic indigestion in which there are formed large quantities of flatus some time after eating. Whether the distention is caused by the fermentation of starches or the decomposition of nitrogenous materials, a minim or two of creosote half an hour or so after eating, or immediately after eating, will often help such cases. Another instance in which creosote is of value is in a case of severe acute gastro-intestinal fermentation, which is often manifested, in the more severe cases, by an actual attack of cholera morbus. The administration of creosote in such an instance not only tends to prevent the vomiting, but to inhibit the production of poisonous products which are developing from the bad food that the patient has been unfortunate enough to take. Here, again, the dose of from one to three minims of creosote, well diluted, proves of value. In those instances in which the vomiting is too intense to permit the swallowing of much liquid, it may be administered in the dose of from one half to one minim in a tablespoonful of water, milk, or brandy, a few drops of this mixture being given at a time. Notwithstanding the laudatory statements which have been made as to the value of thymol, naphthaline, and other gastro-intestinal antiseptics, we believe that creosote is the best one which we can employ, and we doubt, if it is administered carefully, that it is as apt to produce disturbance of the digestion by irritation of the mucous membrane, as some of the more highly praised and more expensive remedies. It is hardly necessary to add that it is important to use the beechwood creosote, and not that derived from the mineral kingdom.—*Therapeutic Gazette.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 24, 1894.

THE SCIENTIFIC VINDICATION OF SPANKING.

IN Lombroso's work on "Les Applications de l'Anthropologie Criminelle," nearly the whole of a chapter is devoted to the Elmira Reformatory of New York. This institution is characterized as representing "the most powerful effort yet attempted for the individual reform of young criminals." It is, according to Lombroso, a practical application of the modern doctrines of criminology, and the most enlightened experience in penology. Lombroso modestly claims that Mr. Brockway, the Superintendent, got his idea originally from the author of "Uomo delinquente." However this may be, the methods of the institution are warmly endorsed. The Elmira Institution has also been described and praised by M. Dubois, in the *Revue pénitentiaire* for 1890; and it has served as a model for other reformatories in Massachusetts, Pennsylvania, Ohio, Minnesota, Kansas, Texas, and California.

Such being the reputation of the Elmira Reformatory, it was no doubt a surprise to all interested in this subject to learn that it had been made the object of newspaper attacks, and finally of a formal legislative investigation; and that charges of cruelty, inhumanity, and stupidity were made against the managers and officers.

In the report of the Board of Managers for the year 1893, the other side of the story is told to us, and we are free to confess that their statements are most convincing. The story of the origin of the complaint and outcry against the institution shows that it was begun by a criminal, who, while out on parole, was arrested and brought back because of criminal acts. This man enlisted the aid of a sensational newspaper, and every possible means was used to discredit the workings of the institution.

The report gives a full explanation of its methods, the class of criminals it receives, and the results which have been obtained. In the charges made, special stress was laid upon the practice of "paddling," or spanking; and perhaps—to parents at least—the most interesting and practical feature of the report is its defence of this procedure. It seems that after every possible moral means of securing good conduct has been tried, there still remains a small percentage of refractory persons who will not obey the rules. For these some form of physical punishment was found necessary, and they selected "paddling," or "spanking," as the most efficient. The report says: "The Managers are familiar with the various forms of compulsory discipline advocated and used by prison governors, now and throughout the history of prison management, and, with this knowledge, they have, from the conviction that it is the most salutary, and at the same time the most humane of them all, adopted and approved that known as spanking. The Managers, notwithstanding the newspaper and other allegations, unhesitatingly affirm that the true history of this treatment at the Reformatory will show that the proper subjugation of the prisoner, by this means, has been accomplished with celerity, and with the least of necessary severity."

They add that "the spanking treatment, if wisely used, especially for youthful impulsive prisoners, neither tends to physical degeneration, nor, as it has been administered at this Reformatory, has it, in any instance, contributed to a sense of moral degradation or hurtful self-depreciation. On the contrary, the records are replete with instances where a trifling spanking has initiated a course of improved conduct and better character-growth, wonderfully like what is ordinarily termed moral regeneration. Many young men, now useful and prosperous citizens, can date their first observable upward progress from the time when they were thus arrested and their activities turned into new channels."

These statements give a certain scientific basis to the still regnant household custom of "spanking." It may be said to illustrate also, in a very persuasive manner, the fact that the inductions of science often corroborate and place on a sound and unsentimental basis certain traditions which have been gradually evolved from the common-sense of mankind. The Elmira Reformatory speaks a word of instruction and comfort to parents, but furnishes a menace tinged with the glow of possible gluteal rubescence to wayward youngsters. For the Elmira Reformatory believes in spanking, and shows by statistics that eighty per cent. of its paroled prisoners are reformed and useful citizens.

PHYSICAL EXAMINATION OF PLAINTIFFS IN ACCIDENT CASES.

THERE has been of late considerable discussion concerning the propriety of insisting upon a physical examination of plaintiffs in damage suits for injury, and much has been said *pro* and *con* regarding the justice and utility of the measure. The statutes provide that such examination should be made when demanded. The subject in the present case happens to be a female, and hence on sentimental grounds the attention of the public is focused upon the individual rights of the plaintiff as a modest and shrinking subject of the law. In spite of the foolish talk in this connection concerning the liberty of the person, the violation of individual rights under the Constitution, and the additionally absurd claim that unnecessary exposure is required, we cannot see how any hardship, or even cruelty, may be the result of such proceedings. It is well known that in almost countless cases of trumped-up damages the actual knowledge of the physical examination of the plaintiff has been the only item of fact upon which a just judgment might have been founded. It is, in reality, the essential element in helping a verdict as to actual damages sustained.

There is always a disposition on the part of the one seeking redress for injuries to exaggerate the degree of

disability, which is in proportion to the amount of damages expected. This is human nature the world over. The sympathies of the jury naturally look upon the object lesson of the enfeebled victim as an impressive and moving one. That such a practice is the encouragement of the worst form of malingering everyone who is accustomed to witness such trials can abundantly testify. In most cases there is no proof of lasting injury and permanent disability save the testimony of the interested party. The evidence is generally quite direct under the skilful coaching of the prosecuting attorney, and the jury is generally on the side of the alleged sufferer. Happily, however, the statute now comes to the rescue in the impartial presentation of the other side. There is no other reasonable way of getting at the real facts. The objection that the obtaining of the same is a blow against individual rights is absurd. In a properly conducted examination there is no more danger of outraging delicacy, or otherwise harming the subject than if an ordinary consultation were held. The mere fact of being a male or a female does not alter the real point of issue, as both are well protected against undue annoyance, unwarranted exposure, and irrelevant interrogation. It is sufficient for the court and jury to know the real extent and nature of disability. Nothing more and nothing less. The only plausible and just way of discovering it in the true interests of justice is by such an examination as the statute directs.

THE SIGNIFICANCE OF YELLOW FEVER AT RIO DE JANEIRO.

The cablegrams published by the press of this city, announcing the appearance of yellow fever on the men-of-war in the harbor of Rio de Janeiro, to the medical mind indicates a condition far too serious to be passed over in silence.

Rio de Janeiro is as essentially a yellow-fever port as the port of Havana. We must remember that for many months the city of Rio de Janeiro has been in a state of siege. Yellow fever to the Brazilian is a home product necessarily familiar. Public health, even in times of peace, is a mere secondary consideration. Given increased filth decomposing under a tropical sun, and we have new foci of disease apart from yellow fever. The latter being recognized as an endemic disease that yearly assumes epidemic character during its season, the hot season now on.

Among the many foreign men-of-war in the beautiful harbor of Rio de Janeiro, the United States has five of her crack ships; yellow fever has appeared on one of the latter, the Newark. The captain of the Austrian man-of-war already has fallen a victim to yellow jack—the scourge of all shipping in yellow-fever ports. Assuming that the many telegrams published are accurate, it means a general diffusion of the yellow-fever poison among the vessels.

The "up anchor" and away now is a trifle late. In any tropical temperature over 65° F. yellow jack can continue its death-dealing mission. In short, several vessels are infected. That such is the case will surprise no student of the disease; the matter of surprise lies in the fact that it has not appeared sooner. All the vessels doubtless have been in daily communication with the shore for mess supplies, etc. The city is an infected centre.

The vessels at Rio have been exposed to a common danger. While we are concerned in the welfare of mankind as a whole, we are particularly concerned in all matters of health relating to the *personnel* of our navy and our new and valuable ships. We know but too well that a ship once thoroughly infected with yellow fever, as a result of months in a yellow-fever port, generally retains the poison for years. We have in mind the Jamestown, her experience at Panama in 1868, and several years later, when she was sent from high to warm latitudes, the disease appeared *de novo*.

If we, as a nation, must mount guard over all the family squabbles of our Spanish-American neighbors, we must be prepared to pay the price in human lives and infected ships. Our brave officers and men must be exposed to the most insidious and dangerous of foes, yellow jack. Standing *in loco parentis* to our tropical brethren is a very large undertaking, and we have yet to learn that yellow fever is an article of international comity.

THE INCREASE OF VASCULAR DISEASES.

During the past decade, in New York City, there has been an apparent excessive increase in deaths and presumably sickness from diseases in which the circulatory system is especially involved.

These diseases are mainly included under heart disease, aneurism, apoplexy, and Bright's disease. The latter class includes probably some cases of local kidney disorder, but, as a rule, Bright's disease means arterial sclerosis and cardiac changes. The mortality in this city from the above causes was in

	1884.	1892.
Heart disease	1,645	2,330
Aneurism	75	56
Apoplexy	628	1,194
Bright's disease	1,928	2,395
Total	4,276	5,975

This shows an increase of 1,701, which is two-fifths of the angiopathic mortality of 1884. The total death-rate increased from 35,044 to 44,329, or about one-fourth. Part of this increase was due to the extraordinary death-rate from pneumonia in 1892, nearly 6,000 persons having succumbed in that year. Leaving out this unusual and accidental factor of increased mortality, the relative increase in serious angiopathies is quite a considerable one.

Some allowances must be made for changes in classification, but the figures we produce are certainly suggestive. It is often asked upon which of the "systems" the stress of modern life most tells. Generally, writers appear to think it is the nervous system, but it may yet turn out to be the emunctories, the chylopoetic, or the vascular apparatus.

St. Mark's Hospital, New York.—The Board of Managers and the Ladies' Auxiliary Society of St. Mark's Hospital gave a reception at their new building, 177 Second Avenue (near Eleventh Street), Saturday, February 17th, from three until six o'clock. An address was made by ex-Judge Noah Davis. A leading feature in the entertainment was a previous understanding that no donations would be solicited.

News of the Week.

Fellow of the Royal Geographical Society.—Dr. Wolfred Nelson, of this city, has been elected a Fellow of the Royal Geographical Society in recognition of his literary labors on Climatology and Physical Geography. This high honor, so well earned, carries with it the congratulations of his friends here and in Canada, his native country. Dr. Nelson is well known to our readers as a frequent and valued contributor to our pages.

Hudson River State Hospital for the Insane, at Poughkeepsie.—At the last meeting of the Board of Managers Dr. J. E. Courtney was appointed First Assistant Physician to succeed Dr. Russell, who resigned.

High Buildings in New York.—We are glad to learn that the subject of high buildings in this city is being discussed with a view to remedying what will shortly be an unmitigated nuisance. Mr. George B. Post, the eminent architect, and himself the designer of many of the tall structures, strange to say, is the one who is first in denouncing the system. The whole matter resolves itself into questions of air and light for surrounding buildings, particularly in narrow streets. Many of the latter are deprived of sunlight entirely, while apartments are so darkened as to require artificial light, and the ventilation is so defective as to cause sickness among the occupants. Every sanitarian must agree that the only remedy is a suitable legal enactment to prevent the erection of buildings beyond a suitable height, consistent with abundance of light and air for the neighborhood. We have small enough air-space in the city already, and we shall have less and less if the present state of things continues to exist.

Death of Dr. James Mitchels.—Dr. James Mitchels died on Monday, at his home in this city. He was born near Vienna in 1812, and was graduated from the University at Prague, and became circuit physician there. Later he was also graduated from the University of Vienna. He came to this country about fifty years ago. Dr. Mitchels was interested in charitable and mutual benefit societies, and organized several in this city. He was a Free Mason and an Odd Fellow, and a member of many other societies. He belonged to the Medical Society of the County of New York, and other medical organizations. He leaves a widow, a son, and a daughter.

Death of Dr. J. E. Wendel, of Murfreesboro, Tenn.—Dr. James E. Wendel died at Murfreesboro, Tenn., on December 21, 1893, aged eighty-one. He graduated from the University of Pennsylvania in 1839, and was continuously engaged in the practice until stricken down, about ten days before his death. Age had not impaired any faculty; his eye was undimmed, his hand steady, and his voice clear and strong. He was actively engaged during all these years and until his last illness. He ministered to five generations of several families here.

The Toledo Medical College and the Illinois State Board of Health.—The Committee on the Administration of the Medical Practice Act submitted their report to the State Board of Health of Illinois, at its recent meeting held January 30th, recommending the recognition of the Toledo Medical College as in good standing before this Board, for the purpose of the Medical Practice Act. The report was unanimously adopted, and it was ordered that the Secretary recognize the diplomas of said college as the basis upon which to issue the State certificates entitling graduates of that college to practise medicine and surgery. The explanation for this is that the Board on a former occasion refused recognition.

New York Medico-Historical Society.—At the anniversary meeting of the New York Medico-Historical Society, held February 12, 1894, the following were elected: *President*, Ellsworth Eliot; *Vice-President*, W. E. Griffiths; *Secretary and Treasurer*, Gordon Frazer; *Editor*, John Shrady; *Diarist*, L. S. Horton; *Committee on Publication*, S. S. Purple, L. S. Horton, H. E. Crampton, with the President and Editor, *ex-officio*.

Lectures on Electricity and Magnetism.—While the application of electricity to the aid and support of medicine is extensive, and electro-therapeutics is daily rising into prominence, there still exists a lack of the technical electrical information which the physician can avail himself of in becoming familiar with the physics, the principles, and the measurement of electricity. In this regard it may interest our readers to learn that, at the request of a number of prominent physicians, Mr. A. E. Kennelly, Vice-President of the American Institute of Electrical Engineers, New York, and Chief Electrician of Mr. Edison's laboratory, has prepared a new series of ten lectures devoted to this subject, which will be delivered weekly at the Mott Memorial Hall, 64 Madison Avenue, City, on Tuesday evenings at 8 P.M. The lectures will be illustrated with lantern and apparatus, and the number of subscribers will be limited to forty.

Trouble in the State Board of Health.—Senators Smelzer, Stapleton, and O'Donnell, the special committee appointed by the Senate, have been directed to investigate the administration of affairs in the State Board of Health. For the past year or so there has been anything but a good understanding between the members of the Board and its Secretary, Dr. Balch, and this is the main reason why an investigating committee was appointed by the Senate. This executive committee of the Board, comprising Dr. W. E. Milbank, of Albany, Dr. F. O. Donohue, of Syracuse, and Dr. H. C. Wolcott, have sent a letter to the special committee in which they say that they will render it all the assistance in their power in making a thorough examination of the Board and its workings. President Donohue's report shows that the registration of deaths was nearly two years and two months behind, and the registration of births two years and seven months behind. Indexing was correspondingly in arrears. Not a single registrar had done the full quota of work. All were more or less behind, some considerably more than others. Yet, in face of this, they were allowed to do extra work, for which they drew extra pay. Copies of cards are given showing that one of the registrars received $2,750 for work which could be done by the piece for $1,665, a loss to the State of $1,085. Another registrar received $2,750 for what should cost only $1,678, a loss to the State of $1,072. After citing a number of these cases the report says:

"The work actually accomplished, for which these clerks were paid big salaries, could have been done for nearly half. To be more particular, there were written up 13

books and 187 pages of deaths, 9 books and 78 pages of births, and 5 books and 56 pages of marriages. At the rate of $200 a book for the births and deaths, and $225 a book for the marriages, the entire cost of the work would be $5,860. There was actually paid for the work $10,750; difference, $4,890. The financial condition of the Board is such that immediate attention must be given to it. For the fiscal year commencing October 1, 1893, there was an appropriation of $40,000, with an unexpended balance on food and drug and tuberculosis appropriations of last year, which were all gathered into one, making an available sum to draw upon for all purposes for the year of $42,836; but on December 14th there was only remaining to the credit of the Board $25,603.65. Over $17,000 had been expended in two months. Of this $6,000 was expended for a general State sanitary inspection, in view of the anticipated visitation of Asiatic cholera, a contingency which was not provided for by the Legislature in its appropriation. If such a condition is allowed to continue, the funds appropriated for the use of the Board will soon be exhausted."

At a meeting of the State Board of Health held in New York on February 9th, it was resolved that: "All registrars shall, as compensation for services to be rendered, receive the sum of $1 per page for registering certificates of births and deaths, and $1.25 per page for registering certificates of marriages." The Board thinks that the orders recently issued will enable the records of vital statistics to be kept up to date hereafter.

The New Reception Hospital for Contagious Diseases.—The new reception hospital of the Health Department, at the foot of East Sixteenth Street, is now ready for occupancy. A year ago the old hospital, which had been used nearly twenty years for the temporary accommodation of patients stricken with contagious diseases, was burned down to make room for the new structure. The new hospital is of brick, is one hundred and forty feet long, and fifty feet wide, and is two stories high. The interior is of glazed brick and it has tile flooring. The cost, including the interior furnishings, was about $85,000. The building itself cost $61,310. Patients will be admitted in the course of a week.

The Freedmen's Hospital.—Dr. Daniel H. Williams, of Chicago, was yesterday appointed by Secretary Hoke Smith as Surgeon-in-chief to the Freedmen's Hospital. Dr. Williams is the leading representative of the colored race in Illinois. He is a graduate of the Chicago Medical College, has been a surgeon of the Chicago City Railway Company, was surgeon of the Provident Hospital for two years, and was physician to the Chicago Orphan Asylum for nine years. As Surgeon-in-chief of the Freedmen's Hospital, he hopes to be in a position to establish and maintain a training-school for colored nurses.

Boxing and the Death of a Student.—The Harvard student injured in a friendly boxing-match is dead. Another victim of athletic sport. The friend who inflicted the blow is now very sorry, and so are all the friends of the dead man. Who will be the next victim? Football has a rest while we are waiting for the answer.

The International Sanitary Conference.—The International Sanitary Conference, now meeting in Paris, has formulated important measures to prevent the Mecca pilgrims from spreading cholera. They comprise a system of inspection and quarantine of all persons going to or from that city. The bearing of European emigration upon the spread of the disease will be duly considered from different aspects, and an exhaustive report thereon will soon be prepared.

A Special Vaccination Train.—The Pennsylvania Railroad Company has sent out a special train with two physicians, who are to go over the whole line to Chicago and vaccinate at each station all the switchmen, sectionmen, gate-keepers, and other employees.

The Berlin Medical Society.—The annual meeting of the Medical Society was held on February 10th, when Professor Virchow was again elected President, and Professors v. Bergmann and Siegmund, Vice-Presidents. From the report it appears that the membership at the end of the year was 914, as compared with 889 for last year. The income of the Society was 28,000 marks, and the expenses 23,000, and the total assets of the Society amount to 90,000 marks.

The Press and Quackery in Medicine.—Not long since, large meetings of women were held in San Francisco for the purpose of protesting against the so-called medical advertising of the daily press. There is a field in this city for the same kind of work. When the ladies of the Health Protective Association have finished their present tasks, perhaps they will turn to medical advertisements.

Permanganate of Potash as an Antidote to Certain Poisons.—It has long been known that permanganate of potash is an excellent germicide, and in some instances an efficacious antidote to snake-venom. In addition to these properties, an Alsatian pharmacist, M. J. Anstal, has, writes the *Journal de Pharmacie* of Alsace-Lorraine, discovered, by means of a series of experiments on dogs, rabbits, and frogs, that it acts as an antidote to the following poisons: phosphorus, muscarine, strychnine, colchicine, oil of sabine, and oxalic acid. Of course, the permanganate must be administered at once to prove efficacious.

Dissection in Public Schools.—The Boston Common Council passed a vote recently forbidding all dissection of animals in the public schools. They subsequently modified the order so as to allow of the dissection of cold-blooded animals.

The Tri-State Medical Journal is the title of a new monthly published at Keokuk, and edited by Dr. James Moores Ball. The three States are Iowa, Indiana, and Mississippi.

Berlin University has just received a bequest of 100,000 marks from the late Dr. A. Düsterhoff.

The State Hospitals for the Insane.—On February 15th, the New York Senate Finance Committee gave the Hospital Managers and Superintendents a chance to answer the statements made last week by the Commissioners in Lunacy. There were present for the Utica State Hospital, Dr. G. Alder Blumer, Superintendent; Trustee George E. Dunham, and F. G. Finks, Counsel; from the St. Lawrence State Hospital, Dr. P. M. Wise, Superintendent; George Hall and George F. Darrell; from the Buffalo State Hospital, ex-Senator MacMillan, from Buffalo. Dr. Wise said the hospital had entered upon a new order of affairs last October with a disposition to overlook any friction that might arise. The commis-

sion, he claimed, had exceeded its legal authority in its interference with the affairs of the hospital. He claimed that the commission discriminated between the different hospitals, and forced the purchase of supplies from certain firms. Speaking of the purchase of wine and cigars in the St. Lawrence Hospital, he said none had been bought at the expense of the State except for entertainment on two occasions. One was the visit of Governor Flower, when there was furnished two kinds of wine, and he directed the steward to buy another. On that occasion two of the Commissioners had been present, and had expressed themselves as much pleased with the entertainment. Commissioner Carlos F. MacDonald, he declared, had told the Superintendent to have a stock of beer on hand, saying estimates for the same would not be stricken out, yet such an estimate was objected to. Neither Dr. MacDonald nor Mr. Brown has scrupled about drinking beer at the hospital.

Ex-Confederates and the Pension Office.—It is stated that the United States Commissioner of Pensions has ruled that no ex-Confederate physician is eligible for appointment as a pension-surgeon. Texas is aroused over this and the Austin District Medical Society has passed the following resolutions with an eloquent preamble:

"*Resolved*, That it is the sense of the medical profession in this section of the loyal State of Texas, as represented by their delegates to the 25th quarterly meeting of the Austin District Medical Society, held in the Capital City of Austin, December 21, A.D., 1893, that the ruling of United States Commissioner of Pensions Lochren that 'no one who was connected with the late Confederate army shall be eligible as Medical Examiner on any United States Pension Board,' is a species of political proscription long out of date, and unworthy an enlightened *free people*, uncalled for, unwise as a policy, unjust to a large class of worthy people innocent of any political sin or offence whatever, a gratuitous insult to the medical profession—a reflection on the honesty, integrity, and capacity of every ex-Confederate surgeon now living; contrary to, and in conflict with, the spirit and pretensions of the Civil Service Reform, and calculated to reawaken bitter sectional feeling, and antagonize an element whose mission on earth is 'peace and good will toward men,' and who, even during the heat of the unfortunate strife, now happily long past, were noncombatants, intent only on deeds of mercy to friends and foes alike.

"*Resolved*, That the Austin District Medical Society hereby protest against a discrimination so causeless, unwise and unjust; and that we call on our distinguished President to either redress the wrong or let the world know why we are thus disqualified."

What Becomes of Physicians' Case-books?—The question has been recently asked, in terms of anxiety not unmingled with suspicion, What becomes of the case-books of a consultant after his death? It is impossible for us, of course, to say what means have been taken to secure secrecy in all such cases, but we may safely infer the general practice from particular cases. The care which is taken by all physicians in large practice to protect their notes from curious persons is seen in such precautions as the private drawer and the padlocked cover. The disposal of such records after the death of the consultant is, no doubt, carefully regarded in all cases. Sometimes the records are made over to a son, or other successor in practice, either to be used for the benefit of the patients, who may return for subsequent consultations, or for the purpose of scientific investigation, as in the instance of the notes of the late Dr. Williams. In two other cases well-known to us the note-books were consigned to a medical friend for scientific uses, and in a third the volumes were consigned to the furnace of the plant houses by a member of the family.—*British Medical Journal.*

New York's Medical Libraries.—It is almost a pity that the two great libraries of the New York Hospital and that of the Academy of Medicine, are not united under one building. That wish has been expressed by some of the Governors, at least of the New York Hospital, in days past. Perhaps the New York Hospital will conclude to build a large library building on Forty-third Street, so that the two collections will be equally convenient to the numerous students.—*Post-Graduate.*

Chemical Congress.—There is to be a Chemical Congress at Brussels in August next.

Dr. E. L. Trudeau, of Saranac Lake, has been given $10,000, with which to build and equip a laboratory for the experimental study of tuberculosis. He has, as well, a fund of $1,500 per year for carrying on the work. With such a scientist as Trudeau at the head we shall expect tangible additions to our knowledge of this most important subject.

Modern Realism in Spanish Literature.—Dr. G. W. Courtney, of Roxbury, sends to the *Boston Medical and Surgical Journal* some excerpts from a modern Spanish society novel literally translated. The following is one of the paragraphs. "All, all had she suffered with resignation up to that moment; the auscultations, the palpations—which she considered shameful—of the accoucheur; the explorations to which she submitted her denuded body and enormous belly, in the lateral or dorsal decubitus, in order that this unknown man might examine the sides or fundus of the uterus—as he said—that he might profane her body! as she felt assured; the stethoscope constantly fixed upon her abdomen in order to perceive and count the fœtal heart; the spiderlike tickling in the innermost parts of her belly, so persistent and annoying that it produced spasms, a species of incessant convulsions; the vomitings; the bulkiness, the monstrous tumefaction of the breasts, with pains so acute that they made her cry to heaven; the unwieldiness of her belly, rounded, fluctuating, convex, really incommodious, which impeded the liberty of her movements; the insupportable tremblings of the fœtus in its prison, at times more constant and brusque; the varicose and œdematous condition of her lower limbs and of her vulva, which made her think of death with pleasure; the vaginal granulations so profuse that they had made of her parts a deposit of pus rather than the external genitals of a woman; . . . the leucorrhœal flow, abundant, viscid, trickling down her thighs, staining the sheets."

Deaths from Carbolic Acid in England.—Between February, 1892, and November, 1893, there were two hundred and thirty deaths in England due to taking carbolic acid. One hundred and seventy-four were suicidal.

Reviews and Notices of Books.

A Treatise on the Science and Practice of Midwifery. By W. S. Playfair, M.D., LL.D., F.R.C.P., Physician-Accoucheur to H. I. and R. H., the Duchess of Edinburgh; Professor of Obstetric Medicine in King's College, etc. Sixth American from the Eighth English Edition. With Notes and Additions by Robert P. Harris, A.M., M.D. With five plates and two hundred and seventeen illustrations. Pp. xx, 697. Philadelphia: Lea Brothers & Co. 1893.

From the editor's well-known interest in obstetric surgery, especially in the operations of Cæsarean section and symphyseotomy, the reader will infer that his notes and additions have been confined principally to these subjects; which is the case, though he has also made useful additions to other chapters, such as those on occiput-posterior positions, extra-uterine pregnancy, rupture of the uterus, etc. A considerable degree of conservatism is still maintained by the author, who is satisfied to allow the chapters on normal pregnancy and parturition to remain practically unchanged. For example, scant mention is made of Hegar's sign of pregnancy (page 157), and the author still seems to give only a partial assent to Schroeder's well-established statement that the *caruncul æ myrtiformes* represent the remains of the hymen after delivery, rather than after simple rupture from coïtion (page 53). On the same page is retained the oft-criticised definition of the perineum, which "separates the orifice of the vagina from that of the rectum," one that was rejected years ago.

The chapter on extra uterine gestation has been brought up to date, and the author takes a sound surgical position with regard to the treatment of carcinoma and ovarian cyst complicating pregnancy. The section on fibroids (page 233) is too condensed for the practical reader.

In the treatment of incomplete abortion the author thinks "a well-prepared sponge-tent the most effectual" (for dilating the os), a statement which will meet with the cordial disapprobation of American obstetricians, as well as the suggestion of allowed retained secundines to remain within the uterine cavity under any circumstances, and, above all, after they have begun to decompose.

In the directions concerning the aseptic management of normal labor a vital point is overlooked—thorough cleansing of the internal, as well as the external, genitals before the initial examination is made. The expression "unnecessary exposure of the person" (page 297), so familiar to us in our student days, has become obsolete to us in this country. How such exposure is lessened by placing the patient on the side, especially when forceps are used, will probably never be comprehended by us.

Few intelligent practitioners would now think of delivering a primipara in any except the lateral posture.

Fig. 111 (page 304), representing "the usual method of removing the placenta by traction on the cord," is unnecessary, since it is hardly applicable to modern practice. We recommend also a further revision of the paragraph on management of the membranes (page 306), in which we are still advised that "they should be twisted into a rope, and very gently withdrawn, so as not to leave any portion behind." It is better not to make any traction whatever, but to wait until the relaxation of the uterus permits them to escape from the grasp of the cervix.

In a note by the editor appended to the chapter on anæsthesia in labor, we read this surprising statement: "In the United States the dangers attending the use of chloroform in obstetric practice have, in large measure, banished it from the lying-in chamber." We do not know on what basis this is stated, but it is certainly incorrect, at least with regard to practical obstetricians in New York. We can hardly believe that this dogmatic assertion is supported by extensive or accurate data. An editorial note on page 314, in which the reader is advised to change a normal pelvic to a cephalic presentation by external manipulation, will hardly be regarded as safe teaching for the general practitioner.

The chapter on occipito-posterior positions is disappointing, in view of the fact that this important subject has received a good deal of attention of late; the note by the editor does not add to its value. The paragraph on the treatment of accidental hemorrhage (page 432) is rather weak. Here, too, there is room for improvement in the light of recent progress in the application of the *accouchement forcé*. The author does well to state that he has had no personal experience in the use of the gauze tampon in the treatment of post-partum hemorrhage, or he would not say that "it is clearly one which can only be resorted to in very intense cases of hemorrhage, when all other means have failed." The ultra conservatism which would prompt such a statement is on a par with the "old-fogyism" which still recommends the use of iron as the most efficient agent for controlling such hemorrhage, contrary to all the rules of modern aseptic surgery.

Transfusion is so obviously an operation of the past, that the reader will marvel to see that an entire chapter is still devoted to it, the only recognition of the modern method of saline infusion being in a short, and not very lucid, paragraph on page 569, supplemented by a still briefer note by the editor.

The author is far from being at home in the more scientific methods of preparing milk for bottle-fed infants. The important chapter on puerperal septicæmia has been revised, but it cannot be said the attempt to "put new wine in old bottles" is altogether successful as regards the paragraphs on treatment.

The separate chapter on pelvic cellulitis and peritonitis is retained, though the author recognizes the fact that a sort of apology is due his readers for its antiquity. It furnishes rather curious reading by the light of modern pathology. The inherent excellencies of Playfair's treatise are so well known that we need not refer to them. It is a matter of regret that in this keen, practical age, the present edition should not be more nearly abreast of recent work in a department of medicine in which theories have begun to melt away under the cogent force of carefully observed and applied facts.

A Dictionary of Medical Science. By Robley Dunglison, M.D., LL.D., late Professor of Institutes of Medicine and Medical Jurisprudence, Jefferson Medical College. Twenty-first edition. Thoroughly revised and greatly enlarged by Richard J. Dunglison, A.M., M.D. 8vo, pp. 1181. Philadelphia: Lea Brothers & Co. 1893.

Dunglison's Dictionary needs no introduction to our readers. It has been the standard of reference for medical scholars for over a quarter of a century.

The twenty-first edition comes to us thoroughly revised and greatly enlarged, with new features treating of punctuation, accentuation, and derivation of terms. Covering the entire field of medicine, surgery, and the collateral sciences, its range of usefulness can scarcely be measured. Perhaps the most valuable feature in the present work is the addition of a vast amount of practical matter bearing upon chemical terms, formulæ, properties, diseases, symptoms, treatment, prognosis, drugs, preparations, doses, effects, medicinal plants, derivatives, effects, poisons, their symptoms, treatment, and antidotes. Also important elaborations have been made under antiseptics, bacteria, eruptive diseases, urine, localization of lesions, ptomaïnes, and leucomaïnes. Judicious condensation and the omission of obsolete terms, have given the volume a reasonably compact form, while the type is commendably clear. We congratulate the present author on the faithful discharge of his onerous duty, and predict for the book another term of future usefulness.

Society Reports.

MEDICAL SOCIETY OF THE HOSPITALS (PARIS).

Hepatic Abscess.—Dr. Petit described the case of a patient who had been operated on for a post-dysenteric hepatic abscess eighteen days after the appearance of the first symptom. The pus from the abscess was perfectly sterile, and no micro organisms could be discovered by a most careful bacteriological examination. The observation would tend to prove that the absence of micro-organisms in the pus of hepatic abscesses of dysenteric origin is not characteristic of chronic abscess, for the same peculiarity may be observed in connection with acute abscess.

BIOLOGICAL SOCIETY (PARIS).

Toxicity of the Urine after Thyroidectomy. — Dr. Masoin presented some conclusions of toxicity of the urine after thyroidectomy. From a large number of experiments he concluded with Dr. Gley that the toxicity of the urine was increased after thyroidectomy. If the animal experimented on is taken with epileptiform attacks the toxicity is augmented during the duration of such attacks. A strict milk diet in no way influences the toxicity of the urine in animals that have had thyroidectomy performed. Dr. Gley contends that these facts prove that the function of the thyroid body is an excretory one, and that it separates certain substances from the blood which, when the thyroid is removed, must be thrown off through other emunctories.

The Innocuousness of the Pneumococcus of Friedlander in the Rabbit.—Dr. Roger, in presenting this subject, said that the general belief in the innocuousness of the pneumococcus of Friedlander for the rabbit was erroneous. He had experimented with two specimens—one taken from a patient who was suffering from what had been diagnosed as acute aortitis; the other had been sent to him by Dr. Netter. He found that peritoneal inoculation killed rabbits in from two to ten days. Intra-venous injection of a very virulent culture caused a mortal septicæmia and death in from twenty-four to thirty-six hours. The autopsy in these cases showed intense congestion of the abdominal viscera, extensive superficial ecchymoses, and infiltration of Peyer's patches. With a less active culture the symptoms ran a subacute course, and were principally those of albuminuria and nephritis, death following in from seven to nine days. These results simulate those obtained from the injection of the bacillus col. commune, but he does not claim their identity. He considers it far from correct to say that the pneumococcus is inoffensive to the rabbit; and he believes, further, that there is a great number of encapsulated bacilli described as a special species that represent simple varieties of the pneumococcus.

PARIS CHIRURGICAL SOCIETY.

Hysterectomy in the Treatment of Prolapsus Uteri.—At a recent discussion of the question of hysterectomy in the treatment of prolapsus uteri, Dr. Schwartz remarked that he had performed the operation once, and although the immediate results of the operation were satisfactory, he desired to call attention to the fact that vaginal hysterectomy is not always such a simple and uncomplicated operation as it is attributed to be. In his own case hemorrhage was stopped only with great difficulty. Dr. Routier remarked that a serious objection to hysterectomy in cases of prolapsus uteri is the tendency to hemorrhage, and that he had abandoned hysterectomy in the treatment of prolapsus uteri for perineorrhaphy and anterior elytrorrhaphy. Dr. Reclus had performed the operation three times for prolapsus uteri, and although he did not look with much favor on the operation from a therapeutical point of view, he had never found the operation a very difficult one; particularly in regard to hemorrhage, which could always be checked by the application of ligatures and artery forceps. In the majority of cases hysterectomy is to be performed, not as the sole curative factor in the treatment of prolapsus uteri, but as a preliminary operation which is to be followed by colpo-perineorrhaphy. Further, he is not at all sure but that the latter operation is, in itself, sufficient in the greater number of cases. It is only in women in whom the uterus is greatly hypertrophied, or the seat of cancerous or fibroid growths, that the preliminary hysterectomy is absolutely necessary.

Trephining.—Dr. Chauvel reported a case of fracture of the skull treated by trephining by Dr. Chupin. The patient, who received a revolver bullet in the occipital region, presented no symptoms on examination. There was found a depression at the seat of the lesion, and a trephine applied there showed that the internal plate of the skull pressed considerably on the dura. The patient recovered.

PARIS ACADEMY OF MEDICINE.

Puerperal Fever.—Dr. Riberolle presented some conclusions concerning an endemic of puerperal fever which he had recently studied. Puerperal fever has existed endemically in the high tablelands of Auvergne for the past fifteen years. The symptoms generally show themselves four to six days after delivery; they are of great severity, and always accompanied by the development of a miliary eruption on the skin all over the body. The patients succumb very rapidly. The disease is communicated by direct or indirect contagion, but as it shows itself only in the form of sporadic cases, the writer concludes that there must be other means of conveying the poison than by the midwife or obstetrician.

THERAPEUTIC SOCIETY (PARIS).

Discussion on Hypnotics.—Dr. Bardet opened a discussion on the comparative value of hypnotics. He classified them as, 1, ethers, of the hydro-carbon group, which includes sulfonal; 2, derivatives of aldehyd, such as paraldehyde, methylal, chloral, chloralose, etc.; 3, aromatics, such as hypnone, whose actions resemble the narcotics; 4, vegetable, such as piscidia. Sulfonal produces sleep without producing anæsthesia, and does not disturb the alimentary tract. Paraldehyde gives good results in the insomnia associated with alcoholism. Methylal he thought very highly of, but its action is fugitive; but it is preferable to chloral, insomuch as it causes no after-dulness and stupidity as does chloral. It is particularly useful in women and children. Chloral, in addition to causing disagreeable after-effects, is often responsible for a cutaneous erythema and irritation of the digestive tract. The derivatives of chloral, such as chloralamid, chloralose, chloral antipyrin, etc., have the advantage that they do not cause this irritation. Chloral, however, is the effective element in these compounds. In concluding he recommended the use of the volatile hypnotics, as they give rapid results and are not followed by gastro-intestinal disturbance.

Treatment of Simple Chancre with Di-Iodoform.—Hallopeau and Brodier claim that the use of di iodoform in simple chancre is attended with as good results as the use of iodoform, and that it is devoid of the drawbacks attending the use of the latter, particularly the smell. It is not irritating, and it should be dusted on several times a day.

ACADEMY OF SCIENCES (PARIS).

The Liquid of Albuminous Periostitis.—Dr. Hugounenq, in reading a paper on the above subject, said that although many communications had been made on this subject since it was first described by Ollier, as yet neither the etiology nor the nature of the disease have been eluci-

dated. An analysis of the liquid taken from two cases which he had recently seen, showed the liquid to be transparent, colorless, or slightly yellow, highly albuminous, of a specific gravity 1.025 to 1.035. It coagulates at 80° C., and in it are seen a number of globules resembling fat. Exposed to the air, it does not putrefy. Chemical examination showed the presence of two proteids, nuclein albumin and serum albumin. The extractives were represented by a very small amount of urea, and four or five times as much succinic acid. No leucin, tyrosin, uric acid, or peptone was found. The liquid of this form of periostitis closely resembles that of hydrarthrosis, and from this it is impossible to distinguish it.

MEDICAL SOCIETY OF LONDON.

Extract of the Thyroid Gland in Skin Diseases.—Dr. P. Abraham reported the results of the use of the extract of the thyroid gland in skin diseases. The extract had been given in 65 cases of psoriasis, 5 of lichen planus, 7 of eczema, 2 of chronic urticaria, 5 of lupus, 1 of prurigo senilis, and 1 of a peculiar papular eruption which superficially simulated adenoma sebaceum. Of the psoriasis cases, 17 might be thrown out as being under treatment for too short a time. In the remaining 48, some definite improvement was noted in 18, but only 7 of these were under treatment with thyroid alone. In 16 the result, as regards the eruption, was practically negative, and in 15 there was actual increase of the eruption while the extract was being given. In 28 patients distressing symptoms were complained of. Of the 5 cases of lichen planus, there was marked improvement in 3. Of the eczema cases 3 were benefited. Neither of the cases of chronic urticaria derived the slightest benefit. Two of the lupus cases showed improvement. The conclusions he reaches are: 1. The ingestion of the thyroid gland has no constant effect in psoriasis, and many other diseases of the skin. 2. In a large number of the cases the results are negative, and in a few the cutaneous lesions are aggravated. 3. In a certain number there is a distinct and marked curative effect. 4. At the present time there are no prior indications as to which cases its administration is likely to benefit. 5. In a considerable number of the cases disagreeable constitutional effects are induced. 6. Age and sex have nothing to do with the action of the remedy.

Fractured Patella Treated by Incision and Wiring.—Mr. Ballance showed two cases of fractured patella in adults, which had been treated by immediate incision and wiring. He had operated in seven cases, all of which were entirely successful. Passive movement should be begun in these cases in from ten to fourteen days, and at the end of a month the patient should be allowed to go about.

Exfoliation of the Mucous Membrane of the Bladder.—Mr. Hurry Fenwick showed a specimen of this condition. The patient had been operated on for acute cystitis by perineal section. The entire mucous membrane of the bladder was withdrawn through the perineal opening, as a white phosphate-encrusted slough. The patient recovered. Cases of this kind are one of the three following subdivisions: 1, Membranous cystitis, in which lymph is cast off from the surface of the bladder and passed in the water; 2, burrowing of tuberculous deposit under the mucous membrane, with shedding of portions of the mucous coat; and 3, entire casting off of the mucous coat of the bladder, together with some of the muscular fibres.

OBSTETRICAL SOCIETY OF LONDON.

Pregnancy and Bright's Disease.—Dr. Herman, in a paper on pregnancy and Bright's disease, said there are two kinds of Bright's disease to which a pregnant woman is especially liable. The first, a fulgurating form occurring with slight premonition, is attended with extremely scanty urine, heavily laden with albumin, and greatly deficient in urea. It occurs principally in primiparæ, and is accompanied with rapidly recurring fits. It runs a favorable course, as a rule. The other is a disease having premonitory symptoms of long duration. Like the first form, it often leads to intra-uterine death of the child. It is accompanied generally by increase in quantity of urine, considerable albumin, and diminution in amount of urea, but not so great as in the first form. Delivery is followed by temporarily increased enuresis, and increase in the urea elimination. When this increase is considerable the patient gets well; when it is not the patient passes into chronic Bright's disease. The cases in which the albumin in the urine is mainly serum albumin generally die; where the albumin is paraglobulin the prognosis is favorable.

SOCIETY FOR INTERNAL MEDICINE (BERLIN).

Stenosis of the Pylorus.—Dr. Landgraf presented a specimen of stenosis of the pylorus following an old ulceration, taken from a man aged fifty-eight. When the patient entered the hospital the symptoms were those indicative of a tumor of the pylorus, but examination of the gastric juice showed the presence of hydrochloric acid in liberal amount. As the patient refused to have an operation performed, lavage of the stomach was practised for relief of the symptoms of indigestion.

Attacks of jaundice alternating with anuria followed, the patient gradually growing weaker. A gastro-enterostomy was then performed, but the patient died in collapse three days later. On post-mortem examination the pylorus would barely admit a sound. It is quite probable that an early operation would have been beneficial.

Lesion of the Heart without Murmurs.—Dr. Leyden showed two heart specimens. One showed aortic insufficiency with extensive changes in the aortic valve; during life no diastolic murmur could be heard. The other preparation showed endocarditis and dilated heart from a patient who died from puerperal sepsis. The clinical symptoms in this case had been very severe, but no heart-murmur could be heard.

Dilatation of the Stomach.—Dr. Boas showed a patient with acute dilatation of the stomach. The man was a gymnast, aged twenty, who after dietetic errors had an attack of acute dyspepsia attended with diarrhœa, vomiting of large quantities of sour material, followed by great thirst and constipation. Examination showed extensive insufficiency and dilatation of the stomach. The patient recovered, and the speaker was of the opinion that in these cases the stomach frequently returned to a normal state.

MEDICAL SOCIETY OF HAMBURG.

Treatment of Empyema in Children.—Dr. Achütz, in presenting a paper on the treatment of empyema in children, emphasized the necessity of costal resection, a procedure which he had practised eighteen times during the last three years. Of these eighteen cases sixteen recovered. The two youngest who were operated on died, one from a broncho-pneumonia of the side not operated on, the other from pericarditis. As a rule, the drain should be left in the pleural cavity for twenty-four days. The time necessary for complete recovery being about forty-two days. The most auspicious time for the operation is the moment the diagnosis is made. All forms of expectant treatment are to be deprecated. Dr. Schütz insists on the incision in the back near the vertebral column at the bottom of the collection of pus and not in the axillary line. The line of incision should be vertical, and the resection of the rib subperiosteal. The cavity is washed with boric-acid solution and the largest possible drain inserted. The deformity from curvature of the vertebral column has not been marked in any of his cases of recovery. He believes that the danger of death from chloroform and from too rapid emptying of the chest in these cases has been greatly exaggerated.

VIENNA MEDICAL CLUB.

A Case of Basedow's Disease.—Dr. Fraenkel showed a patient presenting typical signs of Basedow's disease, in whom the evidences of heredity were extremely marked. The patient, a woman aged forty, had exophthalmos, tachycardia, struma, tremor of the hands, severe diarrhœa, and premature occurrence of the menopause. The father and the sister of the patient had well-marked exophthalmic goitre, and two of her children had died with severe nervous and mental symptoms.

Lumbar Lordosis.—Dr. Fischer made some remarks concerning a case which he had presented to the society some months before. The case at that time presented great difficulty of diagnosis, the only permanent symptom being lumbar lordosis which came on suddenly. The case was by some supposed to be one of progressive juvenile muscular atrophy, and by others of spondylitis. Later, symptoms of meningitis occurred and the patient succumbed rapidly. The autopsy showed basilar tuberculosis, acute hydrocephalus, and in the posterior surface of the spinal cord, at the dorsal and lumbar segments, a soft mass studded with miliary elevations. The lordosis which existed so long as an isolated symptom, was probably dependent on meningeal irritation, in the same way as torticollis is often caused by meningeal irritation.

SOCIETY OF PHYSICIANS (VIENNA).

Cultures of the Bacillus of Influenza.—Dr. Richter demonstrated cultures of the influenza vibrio which had been propagated on agar plates with a stratum of blood serum. The colonies were no larger than the head of a pin. The vibrio is a bacillus that stains with ordinary color stuffs, the poles taking up more color than the centre.

Traumatic Aneurism of the Axillary Artery.—Dr. Ewald showed a woman who in last November fell with a knife in her hand, so that the point went into the left axillary space. Severe hemorrhage followed, but the wound healed in a week. Three weeks afterward she noticed a swelling which continued to increase, and which was accompanied with pain in the arm shooting into the first three fingers of the hand. When examined there was found in the axillary space, beneath the pectoralis major muscle, a pulsating swelling which extended to the infra-clavicular region, the left radial pulse was delayed. A control ligature was placed around the axillary artery, then partial division of the pectoralis major brought the aneurism into view. After ligating the peripheral and proximal end the sac was opened and cleansed. The wound healed by first intention except where the drainage-tube was placed, and the patient made a good recovery.

Congenital Dislocations.—Dr. Ullman presented a patient showing several congenital dislocations. Anterior dislocation of the wrist could be made spontaneously, so that the inferior surface of the ulna could be distinctly felt. A similar condition existed at the elbow and hip.

MEDICO-CHIRURGICAL SOCIETY (EDINBURGH).

Psoriasis and Lupus Treated by Thyroid.—Dr. Byrom Bramwell showed a case of psoriasis in which complete recovery had taken place under the use of thyroid, and two cases of lupus treated by the same substance, to show the improvement which had taken place since the last meeting of the Society.

Eye-Diseases are very prevalent in the Orkney and Shetland Islands. There is no physician in the islands, and the poor natives are dependent upon charitably disposed practitioners of the mainland.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 1, 1894.

D. B. St. John Roosa, M.D., President, in the Chair.

Orthopedic Section.—A report from this Section stated that Dr. T. Halsted Myers had been elected chairman, and Dr. Samuel Lloyd, secretary, for the ensuing year.

Delegates to the State Society.—Dr. L. M. Yale, being unable to attend the coming meeting of the State Medical Society, sent in his resignation as delegate, and on motion by Dr. A. Jacobi, the President was given the power to fill the vacancy.

Bronze Medallion of Louis Pasteur.—Through Dr. Fred. A. Castle, Mr. and Mrs. Samuel P. Avery presented to the Academy a bronze medallion of Louis Pasteur. On motion the gift was accepted and a vote of thanks was extended the donors.

The Prevention of Disease.—Dr. W. W. Potter, of Buffalo, was then introduced by the President in some eulogistic remarks, as speaker of the evening. Dr. Potter had chosen as his subject the "Prevention of Disease," with the hope that further attention might be called to its importance through the large and influential membership of the Academy of Medicine, and that larger audience which it commanded through the various channels in which its transactions were published. The time had fully come for the discussion in all medical societies, by all medical men, of the manifold questions relating to preventive medicine. What he should have to say this evening was not new, and his only purpose in calling attention to the mode of propagation of a few of the more serious infectious diseases, was, if possible, to give further impetus in the prevention of disease.

The first malady, the prevention of which the author then proceeded to discuss, was consumption. This disease had only lately come to be known to the profession as an infectious one. Yet it had destroyed more inhabitants of the globe than almost any other, and only last year proved fatal to more than six thousand residents of New York City. To undertake to prevent its spread by all the means which might be at our command, would involve strict supervision over the food of cows, their stable care, isolation of consumptive persons, especially the destruction of their sputa, prevention of their marriage, etc. It would be especially necessary to prevent the consumption of tubercular meat, whether obtained from cow, fowls, or other domestic animals. The inspection of railway vehicles, steamboats, hotels, would become necessary, and, while at present it would be considered a hardship, yet it was not complained of in relation to small pox and diphtheria, maladies which were less destructive than consumption. It was wrong for a man suffering from tuberculosis to marry a healthy woman and infect her with a fatal malady, and it was equally wrong for a tubercular woman to marry and infect a healthy man. But the dangers of such a marriage did not stop here; children were likely to be born and die of the same malady. He hoped that before long an enlightened legislature would enact statutes prohibiting such marriages. Another step in the direction of prevention was the establishing of separate hospitals and adopting such measures as looked toward the isolation of consumptives. The sputum of tubercular patients must be disinfected as soon as ejected. Martin had examined the dust of one of the most frequented streets of Leipzig, and found the tubercle bacillus in about eighty per cent. of the specimens. Houses, when vacated by consumptives, should receive the most thorough renovation.

Much had already been done toward preventing the spread of tuberculosis, but the author thought the recent reduction in the mortality from this disease was due chiefly to improved sanitary regulations, better nutrition, purer air, and like influences.

Typhoid Fever.—Dr. Potter next called attention to typhoid fever as a preventive disease which carried off

annually a large number of people. In this relation he referred to a fact in history, the first writings of Dr. Austin Flint, describing an epidemic which started from North Boston in 1843. It was due to drinking-water from an infected well. Vaughn had estimated that there were fifty thousand deaths annually from typhoid fever in the States. There was need of further investigation with regard to the mode of its propagation and the best means of prevention.

The two other infectious diseases which deserved special mention on this occasion, because of their widely malevolent influence, were diphtheria and gonorrhœa. Regarding the former, the author thought that if we directed our study to its prevention with assiduity, we might expect success. It was doubtful whether any disease was capable of propagating more sickness and woe than neglected gonorrhœa. Dr. Brewer had reported a case in which gonorrhœal infection, carried by a male for six years, infected a newly married wife; and Dr. Cushing had reported one in which the woman had carried it five years, and then marrying, infected the husband, who had acute gonorrhœa and abscess. It was only during the last few years that physicians had been willing to admit the terrible scourges of this malady. Until recently it had been regarded as a mere trifle, and a chronic gleet was believed hardly to be worth consideration. We must, as a profession, exert ourselves to the utmost to bring enlightenment to the people and enforce the laws of prevention against a disease which he believed to be far more serious than syphilis, and one which played much more dreadful havoc in the community. He appealed to the Academy to formulate and carry out some plan which should have for its purpose the enlightenment of the community, the education of physicians, and the enactment of such statutes as should prevent others than physicians prescribing for, or in any way giving advice as to, the treatment of gonorrhœa.

In his concluding remarks Dr. Potter again appealed to the Academy and its individual members to inaugurate a fashion or crusade which should have for its purpose the prevention of disease, and he would suggest that certain of the general meetings be devoted to this matter to the exclusion of all other scientific work. The example of the Academy was widespread in its influence, and whatever that body asked with regard to quarantine and other sanitary regulations, it could confidently expect would be granted.

The Ocean of Peace.—The President thanked the reader for the felicitous manner in which he had called the attention of the Academy to the need of devoting its general meetings to the discussion of matters relating to prevention of disease. He thought it was quite possible, in the activity of practical work which, as had been suggested, could well be cared for by the several sections, we had at times forgotten the great current, the great stream on which the practice of medicine ought to flow, the one which should lead to the ocean of peace, to the restoration of the community from preventable disease.

Unbroken Mucous Membrane, no Diphtheria.—Dr. A. Jacobi said that of the number of points in the paper highly worthy of discussion he would allude to but one; namely, the prevention of diphtheria. The author had spoken of the law as a means of suppressing contagious diseases, but since in a republic it took much argument to convince the people that, in a given case enforcement by law was not an interference with individual right, he thought physicians should begin by doing what they might in their family practice to prevent the spread of diphtheria, and in thus spreading information among the people they would prepare them for the acceptance of a law which was calculated to lessen suffering and save life. The good which we did the public at large depended upon the good we did the individuals under our care, and since every physician commanded the respect, if not the obedience, of from ten to a hundred families, he could exert a great deal of influence toward the adoption of measures which would diminish the contagious diseases. Dr. Jacobi then dwelt forcibly upon the fact that diphtheria had its origin at the seat of some lesion of the mucous membrane of the throat, nose, or mouth, and that if the epithelium of these parts were kept in a healthy, unbroken condition, the germs of the disease would be thrown off. Diphtheria occurred in persons who had acute or chronic catarrh, so-called tonsillitis, and other conditions in which the epithelium was broken. It seldom occurred in adults, a fact which he accounted for by the comparative absence of hypertrophy of the tonsils at this date. In children suffering from hypertrophy of the tonsils and repeated attacks of tonsillitis, he advised excision. Diphtheria would not occur in the healthy cicatrix.

He gave the same advice with regard to tuberculosis, and even Asiatic cholera, to keep the lining membrane of the air-passages or intestinal tract in a healthy condition, so that the germs of these diseases would be thrown off should they gain entrance.

The Medical Profession can have what Legislation it Wants.—Dr. J. West Roosevelt thought the medical profession could have what legislation it wanted; doctors could do more to shape the policy of state, to preserve the health of the people and of individuals by rational concerted action, than they could effect by any means of treatment which they might undertake. There was, however, one very serious obstacle to overcome, namely, to first instruct the physicians themselves in what they should demand. How many of us considered it worth while to deliberately preach and impress upon the people the fact which had been discussed during the evening? How many of us realized sufficiently the actual dangers of tuberculosis?

Limiting his further remarks chiefly to the prevention of tuberculosis, Dr. Roosevelt did not doubt but what a certain amount of prevention could be secured through legislation, which involved the destruction of tubercle bacilli. Yet, he said, these germs were so numerous and so constantly present that we must look for some more efficient means of eradicating the disease. It was to fortify the body against the development of the germs, should they find access to the mucous tracts.

Dr. S. S. Burt expressed his appreciation of preventive medicine by saying that he scarcely ever wrote a paper without mentioning it. It was as individuals that physicians were likely to do most in this direction. We could not legislate for people before they wanted it. We could not kill all germs, but we could do much to prevent them from coming in contact with the person. He had also felt strongly the importance of building up the system so as to prevent taking disease, and, if possible, to crowd out germs which had got entrance. Indeed, it seemed to him that the best treatment consisted in fortifying the system against further progress of the germs, and making it a poor nidus for those that had entered. He had had a dispensary class for seventeen years, at which he was strongly exposed to the tubercle bacillus, yet he had escaped tuberculosis, a fact which he attributed to keeping himself in good condition. He thought the stamping out of small-pox had been due quite as much to isolation and disinfection and hygienic measures as to vaccination.

Experience as Health Commissioner.—Dr. Joseph D. Bryant said that about four years ago, when he was Health Commissioner of New York City, it occurred to him that it would be a wise thing to open war on tuberculosis, and after consultation with Drs. Prudden, Biggs, and H. P Loomis, a circular was formulated and distributed to the journals and twenty-four leading physicians in the city, asking whether in their opinion, with our present knowledge of tuberculosis, the Board of Health would be warranted in assuming it to be a communicable disease, and in requiring that it be reported like other infectious or contagious diseases, and in taking steps to combat its advance. Of the twenty four physicians to whom this circular was sent, only six replied, some of these after a long period of delay, and only two unquali-

fiedly in the affirmative. The discussion to-night showed what advance had been made. He knew of no physician to day who was not willing to assume that great good would come from isolation or careful surveillance of persons afflicted with tuberculosis. Dr. Bryant said he had also been responsible for the bill requiring the destruction of tuberculous cattle: as a member of the State Board of Health he had induced that body to endorse it, and in consequence it had become a law.

Dr. Potter made some closing remarks. A vote of thanks was then tendered him for his valuable paper.

SECTION ON SURGERY.

Stated Meeting. January 8, 1894.

Joseph D. Bryant, M D., Chairman.

Officers Elected.—Dr. Charles A. Powers, was elected *Chairman*, and Dr. Royal Whitman, *Secretary*, for the ensuing year.

Inguinal Hernia Cured by Macewen's Method.—Dr. F. Kammerer presented a man on whom he had operated for double inguinal hernia by Macewen's method ten years ago. There has been no recurrence. No truss was used.

Gastro-enterostomy for Carcinoma of Stomach.—Dr. Kammerer also presented a woman, past thirty years of age, on whom he had operated about two months ago for tumor, which proved, as had been diagnosed, to be carcinoma of the stomach. Finding it impracticable to extirpate the growth obstructing the pyloric orifice, he united the duodenum with the stomach by an opening about four inches in length, passing three rows of sutures in the manner described by Abbe. There was no doubt in his mind that this was the best mode of performing gastro-enterostomy; it was superior to obtaining union by rings or any mechanical means. The transverse incision through the abdominal walls gave much more room than the longitudinal one, and was resorted to in this instance. Prior to operating, Dr. Einhorn illuminated the stomach for him, which enabled them to define the tumor very well.

Dr. Kammerer also presented two specimens obtained at autopsy, showing the condition of the parts soon after gastro-enterostomy. The sutures had held quite satisfactorily. One patient was operated upon a year and a half ago, and died, not from sepsis or peritonitis, but from exhaustion. The other specimen was from the case of a man operated upon recently, who was very much emaciated, died forty eight hours after the operation, without evidence of sepsis or inflammation.

Pain in Amputation Stump.—Dr. W. W. Van Arsdale presented a boy, eight years of age, who had had his arm amputated after an accident which occurred three and a half years ago. The end of the remaining portion of the humerus pressed upon the soft parts and was twice reamputated. At present the stump was again becoming conical, caused so much pain as to interfere with sleep, and was the seat of sensations of cold.

Conical Stump.—Dr. Shively also presented, in connection with Dr. Powers's paper, a patient, a girl, who illustrated in a marked degree conical stump following amputation through the humerus. In 1890 she was run over by a truck, amputation of the arm was performed, the parents were told that conical stump might develop—this had taken place so that the bone projected two inches or more beyond the healthy skin. The increase in the length of the bone during the four years had been about three inches.

The Modern Treatment of Hemorrhoids.—Dr. James P. Tuttle read the paper. He said he would not have prepared it had not the question been raised lately regarding the comparative value of some of the older operations and newer ones in the treatment of hemorrhoids. Certain forms of this disorder were amenable to the simplest constitutional and local treatment, while others required an operation. Operative measures were more brilliant and more remunerative, and generally were successful, but in many cases, he might say in the majority, they were unnecessary.

Hemorrhoids were either external or internal, the former being in view and connected with the general circulation, the latter occurring within the sphincter and connected with the portal circulation. Some had been denominated mixed hemorrhoids. He divided external hemorrhoids into four varieties, thrombosic, varicose, inflammatory, and connective-tissue piles. In the thrombotic form cold applications had been said to give relief from pain, but he had found sponging with hot water more effectual. The best treatment was excision, laying each tumor open under cocaine, turning out the clot, washing out the cavity with bichloride or boric acid solution, and applying gauze. Pressure would control bleeding.

The varicose form, due to varicose veins about the verge of the anus, seen oftenest in those of sedentary and constipated habit, were often amenable to palliative treatment. Regulate the habit with regard to exercise, diet, and constipation, avoid prolonged stool, lie on the side afterward and apply ice-water, after this apply an astringent ointment on soft lint, retaining it in position over night. The following was a good ointment: Equal parts of officinal ointments of belladonna and stramonium and tannic acid. He had several times cured them by making cross section of the enlarged vein by the cautery at dull heat, but subsequent pain was a serious objection to this method. Operation by crushing was much less painful and quite as successful. He had not tried Kelsey's method by puncture with the cautery, for he had known it to be followed by abscess.

Inflammatory external hemorrhoids were more serious, were more or less club-shaped, single or multiple, and were due to traumatism or irritation proceeding from within or without the sphincter. They developed rapidly and were very painful. Where there was more than one there was apt to be a small fissure between. The treatment consisted in removal of the cause, and operative or antiphlogistic procedure. There was not much choice between ligature, excision, clamp, and cautery methods. If there were also internal hemorrhoids it was generally advisable to stretch the sphincter and remove them first. Leeching and puncturing only added fuel to the flame. Cold compresses sometimes gave relief. Before applying the ointment already mentioned, benefit would be derived from twenty-five per cent. of fluid extract of krameria in water. When pain was severe add a little morphine to the ointment. If an operation were done under cocaine, always be prepared for hemorrhage an hour to three hours afterward.

The next division was that of condylomata, or masses of connective tissue about the margin of the anus, having a mucous, cutaneous, and muco-cutaneous covering, due to irritation, hyperæmia, and hypertrophy of the parts. He had seen them in both malignant and specific disease, but did not consider them as evidence of any particular disorder. They were liable to become inflamed from traumatism or irritation of the anus, then swelled and became exceedingly painful, sometimes ulcerated. The vascular element was very small. Careful regimen, application of cold, and avoidance of injury would keep them quiescent, but would not cure them. If they did not annoy the patient they should be let alone; if they did, they should be removed, and it was better to remove them when quiescent. He operated by clamps, crushing, or by scissors. He preferred palliative treatment until inflammation had subsided, and then resorted to crushing. It was rarely necessary to resort to operative treatment in any form of external piles except the thrombotic; palliative treatment was sufficient.

Internal Hemorrhoids.—These were varicose or capillary. The point of hemorrhage in the capillary form was not often from the summit of the tumor, but from the sulcus, and the author thought it was owing to this fact that cauterization often failed to check bleeding. The

tumors were too small for ligature, clamp, or crushing. The most common method of treatment was the application of nitric acid to the bleeding point. But there was this objection to it, that it was impossible to limit the action of the acid, and it therefore sometimes caused ulcers of considerable size. He had recently adopted in its stead electro-cautery through means of a small, round, platinum electrode, the parts having first been cocainized. He preferred this to the Paqueline cautery or curettement with Volkmann's spoon, two methods which required general anæsthesia.

There was a mixed form of hemorrhoids which often would disappear under local applications and general hygiene.

The operative treatment of internal hemorrhoids consisted of injections, clamp and cautery, ligature, and Whitehead's operation. Regarding injections, the object was to produce inflammatory induration and subsequent absorption. By some, however, it was applied with a view to produce sloughing in the tumor, which seemed to the author unsurgical and dangerous. Thorough antisepsis and cleanliness were called for. The needle should be introduced from the base of the tumor to its centre, point neither downward to the connective tissue, nor ending against the mucous membrane. The blood should be pressed out with the finger. Then inject two minims, never more than four minims, of a solution composed of one drachm and a half of carbolic acid, half a drachm of salicylic acid, a drachm of biborate of soda, and a sufficient quantity of glycerine to make an ounce. The solution was unsafe unless perfectly clear. This treatment caused no pain, did not confine the patient, and if it did not cure it certainly gave immunity for a long time. He had not seen hemorrhage, constriction, or injurious results in any of nearly a thousand injections. He attributed this freedom from evil results to strict antisepsis, the weak solution, and small quantity injected. Only a few of the cases had recurred, even after three or four years.

In some cases a more radical operation was necessary, and the clamp and cautery seemed about to supersede the ligature. The piles should be counted and located before the sphincter was dilated, for after dilatation the whole hemorrhoidal area became so congested and swollen that it was difficult to outline them. Dragging the sphincter forcibly apart with the thumbs was too violent a procedure. He preferred gradual introduction of the fingers into the rectum, which acted as a bougie. The hemorrhoid should be grasped in the clamp parallel with the gut, not across it, then cut off with the scissors, and the raw surface be seared with the cautery at red heat, the object of the cautery being to stop hemorrhage and not to destroy tissue. Deep burning would be apt to produce hemorrhage and sloughing. In over five hundred cases so operated upon the author had not seen hemorrhage of moment, death, or cicatricial narrowing of the gut. The patients usually were not confined more than four or five days. Crushing, without the use of the cautery, was not so safe as the method just described, and was called for only in few cases. As to the ligature, he had had no particular failures with it, but there were disadvantages attending its use. The operation could not well be made aseptic, it required considerable time, it was very painful, the patient often suffered a week or more, often it necessitated the use of the catheter, it endangered secondary hemorrhage when the ligature cut through, it was liable to leave an ulcer, it confined the patient to bed a long time. As between Allingham's operation and transfixion, the latter seemed the less dangerous, the ligature was less likely to slip off.

Excision, or Whitehead's operation, the last candidate for favor, consisted in snipping off the tumors and stitching the edges of the mucous membrane together. But in this area lay the circulatory apparatus of the lower end of the rectum, and he was not convinced that the tissue removed could be taken away with immunity. In patients operated upon by others by the Whitehead method he had seen stricture in two, ulceration in two, prolapsus and erosion in one. It was sometimes followed by apparent drawing upward of the cutaneous tissue, so that it became macerated and caused pain and fetid odor. Its success depended upon perfect asepsis, immediate union, absence of tension, and conditions some of which were liable to fail and spoil the operation.

Dr. Willy Meyer opened the discussion. He preferred the ligature to the clamp-and-cautery method, and said the objections which had been offered to the ligature seldom held. The patient was out on the twelfth day. The Whitehead operation was an ideal one in cases in which it could be practised, that is, with hospital conveniences, but in private practice he would prefer the ligature or clamp method.

Dr. Samuel Lloyd wished to corroborate what Dr. Meyer had said regarding the ligature and Whitehead operation. He was not very favorable to the cautery unless it were necessary to check hemorrhage. Whitehead's operation had been very successful in his hands, and he thought he would prefer it also in private practice. He put in a light ligature and then sutured the mucous membrane on top.

Dr. T. H. Manley agreed with the author that a large proportion of cases of hemorrhoids called only for palliative, not operative, measures. Many cases could be cured without operation, while all operations likewise failed sometimes. Hemorrhoids, like varicocele, was often due to an inherited tendency. Usually cocaine anæsthesia was sufficient. For varicose hemorrhoids he dilated, turned the hemorrhoid out of the anus, and twisted each one on its base and crushed it. Resorption followed. This method was safer than operative procedures, was not, like them, liable to be followed by cicatrization, and was usually efficient. Whitehead's operation was called for only in exceptional cases.

Dr. Kammerer had had some experience with Whitehead's operation, and expressed the opinion that it should be resorted to only in severe cases.

The Chairman, Dr. Bryant, spoke favorably of the ligation method. Of course the mucous membrane should not be removed in the transverse direction, and patches should be left between the excised portions. With such precautions contraction would not follow. If the hemorrhoids were small, he used catgut; if large, and there was likely to be some strain on the ligature, he used silk. As to the danger of Whitehead's operation, it was hardly deserving thought when Whitehead was able to report three thousand operations without a death.

Dr. Tuttle, in closing the discussion, said his main objection to the ligation method was the length of time the patient was confined to the house. He characterized the tube-tampon, which some used to prevent contraction, as the "most damnable thing ever put into one's backside." It was extremely painful and did no good, for contraction did not take place until after a cicatrix began to form.

Further Observations on the Physiological Occurrence of Conical Stump after Amputations in Children.—Dr. C. A. Powers read a brief paper bearing this title. His first observations had been communicated to the Section in March, 1890, at which time he related cases of conical stump after amputations in children which could not be accounted for by any fault in technique, but which was attributed, in accord with the views of Dr. Bull and some others, to physiological growth of the bone in excess of growth of the soft parts. The amendment which he had to offer to the views then expressed was, that inflammatory deposit might take place at the end of the bone from pressure against the skin. This inflammatory deposit, however, contributed only slightly to the length, the main part being due to physiological growth of the epiphyseal cartilage. Additional cases were cited in proof of this view, and photographs were shown. The stump, an inch and a half in length, which had been removed in one case, was examined by Dr. Ferguson, who reported that he regarded the changes in the end of the stump as due to development of the bone in a physiological way, and to pressure upon the soft parts.

We were forced to accept the conclusion, he said, that amputation through the upper half of the humerus or leg of a young child would probably be followed by a conical condition of the stump, and the parents might well be notified of that fact at the time of the operation, and be led to expect in two or three years that further resection of bone would be necessary, and that even this might have to be repeated in the course of time.

Dr. Whitman said he had seen several cases of conical stump.

Dr. Lilienthal said he then had under observation a man, aged twenty-two, who had painful ulceration of conical stump following amputation at the age of fourteen years.

Dr. Van Arsdale asked whether conical stump was the rule or the exception?

The Chairman, Dr. Bryant, remarked upon the rapid growth of the bony stump in Dr. Van Arsdale's case where two resections had been made within a short period; said all doubt seemed to have been removed as to the main growth of the humerus taking place from the upper epiphysis, but the wonder was that all healthy arms were not out at the elbow!

Dr. Powers replied to the President's suggestion by saying that nearly the entire growth of the humerus was from its upper third, and went on to take place when the lower two-thirds were removed, just as it did in the healthy arm, whereas each section of the soft parts, having but its own growth, the third remaining fell behind that of the bone in increased length by two thirds, or in proportion to the amount removed.

Portable Sterilizer for Private Operations. — Dr. Willy Meyer exhibited a portable sterilizer, made of nickeled copper, also one of plain copper, with tray for instruments and pan for towels and cotton. There accompanied it an alcohol-lamp, with half a dozen burners. The sterilizer was long enough to admit obstetric forceps. Filled with all the paraphernalia necessary for an operation at a patient's house, it was put into a canvas cover and transported like a valise. Immediately on arriving at the patient's house two quarts of water, with crystallized soda, were poured in, covering the instruments, while the towels in the pan above were exposed only to the heat of the steam after the lamp had raised the temperature sufficiently high. The whole time required for sterilization was about thirty or thirty-five minutes. A fuller description will be given in a future issue.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE GYNECOLOGICAL SOCIETY — PROTEST OF ITS PRESIDENT—SCHOOL OPHTHALMIA—DANGER OF ITS SPREADING —AN ALARM TO HIGHER SCHOOLS AND THE GENERAL PUBLIC—SPREAD OF SMALL POX AROUND HOSPITALS— DISCUSSION AT THE EPIDEMIOLOGICAL SOCIETY—SPONTANEOUS DISAPPEARANCE OF ABDOMINAL TUMORS.

London, February 3, 1894.

The British Gynecological Society lately celebrated its annual meeting by a dinner, when the President, Mr. Bowerman Jessett, occupied the chair. He ventured, in the course of his speech, to give expression to a feeling often talked of in more private assemblies, viz., the appearance of jealousy in some quarters at the formation of this society. Simple rivalry in such associations may do good, but downright jealousy is absurd, though in this case no doubt it exists. The Obstetrical Society, or rather certain members of it, considered there was no room for the Gynecological, and these members seem aggravated at its success. They seem, too, to have been able to influence some of the journals to exclude reports of the younger society, and against this "boycotting" by the editors in question, Mr. Jessett uttered a quiet and dignified protest which may, perhaps, have the desired effect. The midwifery section of the profession have long been proverbially credited with being the most jealous of each other, and many a joke at the expense of the "ladies' men" has been founded on their assumed sensitiveness. I have occasionally referred to the doings of the Society, which is vigorous enough to maintain its own journal. Dr. Savage has been elected president for this year.

A very grave indictment against the more well-to-do classes has been drawn by Mr. Jonathan Hutchinson. At the last meeting of the Ophthalmological Society he charged them with indifference to the consequence of crowding the children of the poor in schools and workhouses, which has resulted in a great spread of ophthalmia. Mr. Hutchinson has special experience, and while disclaiming all wish to be an alarmist, he raises his voice in serious warning. School ophthalmia, he declares, has at length invaded some of our great public schools, and, unless the greatest precautions are at once adopted, will be disseminated by the boys throughout the middle and upper ranks of society.

Another way in which this disease is spread is the practice of sending home soldiers who are suffering from granular lids, a line of conduct which Mr. Hutchinson calls reprehensible. If the facts be all as set forth, we may soon cease to speak of "school ophthalmia" or of "military ophthalmia," and adopt some more general term, such as family ophthalmia. If the disease owns no predisposing conditions, but attacks indiscriminately those who are exposed to the contagion, there is assuredly no little danger of its spreading throughout the community wherever it finds a lodgement. Obviously, close small rooms, overcrowding, and other conditions hitherto said to be predisposing, are precisely those which favor direct contagion, and the virulence of the contagion in schools and barracks may be accounted for by the habits which prevail in such places. Isolation of every case of inflamed eyes and a careful examination of the lids before the pupil is allowed to return, are the means recommended for prevention by Mr. Hutchinson, and he opposes the breaking up of a school as a measure which would only disperse the disease through the families of the scholars.

Of course, a paper of this importance by an acknowledged expert, would receive the attention it deserved, and the discussion which arose was adjourned to the next meeting. Of those who spoke, Dr. Sydney Stephenson, who has charge of an isolation school for 400 children, said that in June last the number admitted had fallen to 100, and cases were therefore admitted from other districts. He had examined 14,000 children in different schools, and found 94.5 per cent. showed more or less follicular bodies in the lids, only 4.5 per cent. being free. Does not this look as if this slight condition might almost be termed normal? Dr. Stephenson formerly regarded the follicular affection as an early stage of trachoma, but he found this was not so, for follicular conjunctivitis does not develop, and out of all the cases named only 0.5 had true trachoma. Mr. Nettleship thought unnecessary alarm had been raised by the discovery of widespread disease of the lids; but he did not think there was a serious amount in the higher-class schools, and what there was presented a mild form. The systematic examination now common discovered cases which would formerly have been overlooked.

The question of the aërial convection of small-pox from hospitals has been brought before the Epidemiological Society by Dr. McVail in a masterly address, summing up the evidence that has been adduced with judicial care. He was unable to exclude aërial convection from the causes of the spread of the disease, though he thought that in almost all instances personal intercourse concurred in producing the outbreak. Such circumstances as the presence of susceptible persons in the population, the meteorological conditions, and the position and arrangements of the hospital were important—the last perhaps the most important of all. Dr. Savill said that at Warrington, when the cases were transferred to the new

hospital, the distribution of the disease seemed to follow, but bore no relation to other courses, though a very close one to human communication. Dr. Sweeting said that at Fulham, on the admission of small pox, the fever cases were revaccinated, except six or eight, and these took the disease in spite of the utmost precautions, including the use of the telephone to prevent communication between the parts of the building. This discussion was also adjourned.

At the Royal Medical and Chirurgical Society, on January 23d, a paper was read by Mr. J. Greig Smith (Bristol) on the "So-called Spontaneous Disappearance of Solid Abdominal Tumors." Three cases were recorded, the common leading features in which were the presence of a solid tumor in the abdomen, absence of pyrexia, clinical evidence of malignancy on abdominal section, and ultimate disappearance of the tumor with complete restoration to health. The first case was that of a young man aged twenty-five. Intestinal obstruction existed, due to a solid tumor as large as a cocoanut situated in the lower abdomen. The tumor, being on inspection diagnosed as malignant, and being inherent to intestines, was not disturbed. Enterostomy was performed for the obstruction. The tumor slowly diminished in size, and six months later, when the abdomen was opened for the performance of enterorrhaphy, it was found to have disappeared. The patient, after four years and a half, continued in good health. In the second case, that of a woman aged fifty-five, the tumor lay in the umbilical region, and was adherent at and around the umbilicus. It was globular in shape and as large as a child's head at birth. On abdominal section the intestines were found to be adherent to its surface on one side. Diffusing malignancy was diagnosed, and no attempt at removal was made. A small collection of muco-pus at the umbilicus was evacuated, and the slight discharge from a fistula which formed there continued for over two years. The tumor disappeared, the sinus closed, and the patient was now quite well. A girl aged nineteen was the subject of the third case. Here the tumor was as large as an eight-months pregnant uterus, filling and distending the upper and right side of the abdomen, but not dipping into the pelvis. On abdominal section the tumor was diagnosed as malignant and unremovable. A fecal fistula formed, the tumor gradually diminished in size, and ultimately disappeared. The intestinal opening was closed by operation, and the patient was at present in good health. Comparative observations were made on solid tumors of myomatous, tuberculous, and inflammatory nature, which in the writer's experience had been found to disappear after operation. An explanation as to the origin of the tumors in question was made to rest on the process of phagocytosis and the heaping up of embryonic protective cells around a minute fistulous opening communicating with intestine. Cure was accidental, but not spontaneous, depending in one case on a diversion of intestinal contents, and in the two others on an external opening of the fistula.

Dr. Church remarked that it was just in such cases as those under discussion that the quacks made capital. He suggested that some inflammatory lesion or enlargement of a Mechel's diverticulum, might be the cause of some instances.

Mr. Alban Doran said that in cases of chronic peritonitis, accompanied by adhesions of intestine, and by the accumulation of scybala, clinical signs might arise which closely resembled those of solid tumor. Chronic tuberculous peritonitis was not rare in tolerably elderly people, and as a result masses of inflammatory material might be formed on the surface of the intestine; these might subsequently disappear, and the temperature might remain for long periods little if any above the normal. Such inflammatory formations simulated a semi-solid or semi cystic tumor, and were hard to differentiate even on inspection, but cancer and sarcoma did not tend to get better by themselves; when external they might slough, but such a condition occurring within the abdomen would certainly prove fatal. In chronic peritonitis in adults and tuberculous peritonitis in young men or women, the changes in the apparent tumor were most remarkable, and might take place in a very short space of time.

Mr. Bland Sutton said that since 1891 he had had four of these cases of disappearing tumors under his care, but in none of them had he to open the intestine. They had all been associated with the bowel, and he thought that in the manipulations incidental to an exploratory operation, adhesions had been broken down which had prevented the passage of intestinal contents, and, this having been relieved, the inflammation had subsided. He did not believe in the spontaneous disappearance of any connective-tissue or cancerous growths; and the cases spontaneously disappearing of myomata which had been recorded were based on clinical observations alone.

Mr. Barker remarked that most of the disappearing tumors had been referred to the abdomen, but he mentioned one which grew in the neck.

Sir W. Priessley alluded to the well-known changes undergone by fibroid tumors of the uterus. The tumors under discussion turned out to be more benign than had been expected, and thus resembled many tumors and ulcerations of the breast or uterus which bore every appearance of malignancy; and yet, to the surprise of those who had made the diagnosis, they disappeared and the patients recovered. The whole question was as to the nature of the tumor, for as to their existence there could not be a doubt. He knew of no tumors in the abdomen or pelvis, which could disappear in the way described, that were not of inflammatory origin. They need not be accompanied by a high temperature, for large tumors and extensive areas of suppuration might occur without febrile reaction or special local signs.

Mr. Barwell inquired whether odorous pus was found in all the cases. He had seen many cases of chronic peritonitis associated with suppuration, unaccompanied by fever or constitutional disturbance.

Mr. Greig Smith said in reply, that the discussion had helped in the understanding of these difficult cases, and would do away with the theory that solid abdominal tumors might spontaneously disappear after an operation. There was nothing spontaneous about the process, which was simply a question of cause and effect.

OUR ROMAN LETTER.

(From our Special Correspondent.)

HOW TO REACH ROME—RAILWAY TRAVEL ON THE CONTINENT—FEES—CUSTOM-HOUSE EXAMINATIONS—BAGGAGE—SLEEPING AND DINING CARS.

ROME, February 2, 1894.

ALL roads lead to Rome, some almost as the crow flies, others by a more circuitous route, though quite as expeditiously. The sea passage varies, according to the route and boat selected, from six and a half to fourteen days, and the railway journey, from the port of arrival in Europe to Rome, from five to forty-eight hours. The expense of the round trip from New York, including a ten days' stay in Rome, will run from $200 upward. Probably most of those attending the Congress will go and return by one of the Mediterranean lines direct to Genoa or Naples; but for those with larger purses and more time at their disposal it would be more pleasant to go by way of the Mediterranean and return from one of the northern ports (Hamburg, Bremen, Rotterdam, Havre, Southampton, or Liverpool). Most of the steamship lines as well as the railways on the Continent offer tickets to the members of Congress, and in many cases to the families of the members also, at greatly reduced rates—in some cases as low as one-half the regular fare. In order to secure this advantage, however, the member must have paid his registration fee and have secured the necessary documents in proof thereof. If the traveller is sure of the route he will take, some trouble and annoy-

ance may be saved by procuring Cook's or Gaze's tickets for the entire journey from his home to Rome and back. The only objection to this is that the traveller cannot alter the route first determined upon under pain, in most cases, of forfeiting the amount paid for the tickets. He can, of course, make side excursions from any station where a stop over is permitted, but must return to the same station and continue his previously arranged route from that point. Bearing these conditions in mind, the purchase of circular tickets will save the traveller much trouble and inconvenience, especially if he be unacquainted with the languages of the countries through which he must pass. It may be well, perhaps, to say that the holder of a Cook's ticket may travel as he chooses, and need not necessarily proceed with a personally conducted party.

As the conditions of travel in Europe differ in many respects from those in this country, a few hints may not come amiss to those visiting the old world for the first time. And first, as to the question of fees—an annoying but universal custom to which everyone must submit with as good grace as possible. Americans in Europe usually make one of two mistakes: they either fee too lavishly or not at all. The sulphurous fumes of invective that follow the latter in their peregrinations is something too awful for any but those with the strongest nerves and the most profound disbelief in a future life to contemplate. He who fees moderately but justly is fully as well served as the one who scatters gratuities recklessly, and is perhaps rather more respected by the recipients of his bounty. On the steamer the bed room steward, the table-steward, and the boots all expect fees. For a voyage of a week to ten days, $2 to each of the former and $1 to the latter (if he has brushed your clothes or polished your shoes), would be a fair amount if no extra service has been rendered. A man travelling with his wife would be expected to give a little more to each of the stewards, and also to fee the stewardess and the deck steward, who looks after the steamer-chairs and brings meals to those too ill to go down to the saloon. It is unnecessary to buy steamer chairs, as they can usually be hired for the voyage on the pier, or from the deck steward on the steamer. It will be wise, however, to make inquiries concerning this before sailing, for a steamer-chair is a great luxury, if not an absolute necessity, on a long ocean voyage. Upon arrival in port the baggage is examined by the customs officers, as it is also at every frontier station in passing through Europe. This is usually a mere formality, although sometimes a very disagreeable one, if the traveller happen to cross a frontier in the night time. Everyone must leave the car and enter the custom-house whither his luggage is carried by the porters. He must always be present at the examination of his baggage, and can delegate the duty to no one else unless he be absolutely prevented by illness from leaving the car. The examinations are not strict, and as a rule the only things upon which duty may be levied are tobacco and spirits. In most countries a reasonable number of cigars or cigarettes (say twenty-five cigars or fifty cigarettes), or a quarter of a pound of tobacco, will be passed free, but in Italy the legal allowance is only seven cigars, or as many cigarettes as the officials may consider sufficient for a single day's consumption. If the passenger shows a readiness to open all his luggage and keeps his temper, he will almost invariably find the customs officials civil and easy to deal with. The railway porter who carries the hand baggage to and from the examining room, expects a fee equivalent to five cents or more, according to the amount. The same fee is looked for in all stations for carrying luggage to or from the cab or omnibus; if there is also registered luggage, about twice as much should be given.

In some countries the railways carry fifty six pounds (25 kilos) of baggage free; there is always a registration fee of about ten cents a package), but in others every pound must be paid for, except valises and satchels, that can be taken with one into the railway compartment. On through journeys baggage can be checked (here called registered) through to destination and the passenger need have no concern about it until his arrival, except when crossing a frontier, when he must be ready to open it for inspection to the custom-house. When it is not registered he must attend personally to its transfer at every change of cars, and must fee the porters who carry it. From what has been said above, it will be seen that he who travels with little baggage, preferably hand-baggage that he can take with him into the car, will avoid much annoyance and expense.

On most of the night express trains there are sleeping-cars, of which the traveller with first class railway tickets can avail himself by the payment of about twenty per cent. above the ordinary first class fare. On the day express-trains there are dining-cars, in which first- or second-class passengers can breakfast for about eighty cents, or dine for one dollar. Wine is always extra at these meals, and the traveller is expected, though not obliged, to purchase a half-bottle of wine or mineral water. The same is expected of him at all *table d'hôte* meals in hotels or restaurants, except in France, where a mediocre table wine or a syphon of mineral water is included in the price of the meal. The fee to the waiter should be from 5*d*, ten per cent. of the charge for the meal. Dining *à la carte* is usually a much more expensive way, and it is advisable for the traveller to take his meals, as a rule, *table d'hôte* (*à prix fixe* is the more common term in Europe, *table d'hôte* having a slightly different signification).

In most cities where one would be likely to stop overnight, or for a longer stay, each hotel has its omnibus at the station. The fare is usually slightly in excess of the legal rates for cabs, but one who is not familiar with the place and the ways of the cabmen had better take the omnibus, nevertheless. The hotel porter at the station will take the check for registered baggage and see to its delivery at the hotel—for which a charge will be found in the bill. English, French, and German are spoken by the porters of all the first class hotels in the larger cities of Europe, and one who is ignorant of any language but his own can travel very comfortably by the aid of pantomime and a little copper anywhere in Western Europe. A final word concerning railway travel. Everywhere in Europe there are first- and second-class railway compartments, and in purchasing tickets it is necessary to state what class is desired. If there are only men in the party, second class is comfortable enough anywhere for day travel; but if a sleeping-berth is wanted at night, a first-class ticket must be taken, as passengers of this class only are admitted to the sleepers, at least in France and Italy. In Germany and Austria, passengers with second-class tickets are given accommodations in the sleepers upon payment of the extra fare. If ladies are in the party, first-class tickets should be taken in France and Italy, as the second-class compartments are not very comfortable. In Germany and Austria, the second-class cars are comfortable enough even for ladies, though naturally not as exclusive. For long journeys so called, mixed tickets may be taken, that is, tickets permitting of travel first-class in France and Italy, and second-class in Germany and Austria.

Information as to the exact rates on the steamers and railways, and the reduction allowed to actual members of the Congress, as well as to the dates of sailings, and the length of time required by the different routes to reach Rome from any city in America, can be obtained from any of the agencies of Thomas Cook & Son, or of H. Gaze & Co. Those desiring to secure accommodations in Rome should apply at once to Cook's agents, who have secured a limited number of rooms in various hotels and boarding-houses in the city for members of the Congress.

Skin Grafting.—If we wish a skin-flap to adhere to a new surface by first intention, or agglutination, we must be sure that it is free of all areolar tissue and properly fixed in its new place.—Wolfe.

"THE PROFESSOR OF WIND AND WATER" AND HIS MISLEADING STATEMENTS.

To the Editor of the Medical Record.

Sir: I read in the Medical Record of February 3d an item entitled "The Greatest Consultation in History." I regret that you should have fallen into so grave and absurd an error as to believe such news of these poor writers of "the veracious daily press."

I will state that, as a matter of fact, the mother in-law of the Mikado of Japan has not "recently been ill," and that if such were the case, we have in Japan a dozen of the ablest physicians in special attendance on the imperial household, and no less expert than the ablest of American doctors, who would be called to attend her.

From the very commencement of Japanese history, that is, from two thousand five hundred years ago down to the present time, there was never the case of so many physicians being called to consult in even an emperor's sickness.

As to the statement that a "Buddhist priest" attributed the imperial mother-in-law's illness to the introduction of the railroads, I might say (if such statement were true) that the Buddhist priests, as a class, are friendly to the introduction of the railroads. They do not oppose them, but, on the contrary, advise the building of them, and are only too glad to avail themselves of their facilities and conveniences.

Even more than this, the simplest person of our land, the most ignorant of our lowest classes, bears no ill will to so progressive an invention as your iron way.

Japanese statistics of 1892 show that in a land area of 160,000 square miles we have 1,400 miles of railroad laid. There are in process of building, not yet completed, more than a score of railroads.

It seems to me, therefore, that the statement you quote, and which you apply to Japan, must refer to China. In China it is not unusual to have congregated for consultation, in cases of imperial sickness, four or five hundred doctors. But there even, so many are called not for purposes of actual consultation or participation in service to the patient, but for mere ceremonial dignity.

Most of these doctors never know anything of the condition of the patient; they are but actors in a grotesque play of imperial pomp.

The personage whom your item calls "a Buddhist priest," was doubtless, in Chinese philosophy, the figure of mind, the representative "professor of wind and water," classified with Taouism by the common people.

Chinese Taouists claim to be true followers of the very ancient philosopher called Laoutse. The more intelligent classes, those who have studied deeply, do not admit this. As defined by Count d'Escayrac de Lauture the peculiar faith of Taouism is "practically a religion to which belong the doctrines of Confucius and the objects of cult of Laoutse and precepts of Buddha."

In one feature Taouists resemble the ancient Alchemists, they seek to convert common metal into gold and mercury into the medicine of immortal life.

The fundamental principles of this philosophy are those of the five elements, the principles of negation and positivism—water, fire, wood, metal, earth. Phenomena, as well as human fortunes, are analyzed by the motions or the interchanges of these elements. Besides this they believe these elements to have their own spirits or gods, and they fear to antagonize their supernaturalism.

The professor of wind and water is an offshoot from this doctrine. He specially controls the relations between these two elements, air (wind) and water, and all human affairs. He is believed in by most low class Chinamen and the superstitious ones of the high classes. A representative of the professor of wind and water teaches the doctrines I have mentioned, and worships and mediates for the believers to the spirits of these two elements.

Now, the common people of China believe that if they erect edifices—such as tombs, temples, towers, houses, or railroads—in a wrong situation, that is, in opposition to the negative or positive character of the elements, wind and water, of the particular locality, the owner or builder of such edifices will be punished by the spirits with great calamity—perhaps with fire, famine, pestilence, or other misfortunes.

These conditions of superstitious belief of the philosophy of the Chinese are now the greatest obstacle to the building of railroads in that empire. There are but a very few miles of railroad in China, including Formosa, which is the island of China nearest Japan. Against the building of two hundred miles of railroad the greatest opposition was encountered on the part of common people through their belief in the spirits of the elements to which I have referred.

I read often in Japanese newspapers that it is prophesied in China by this wonderful professor of wind and water that the imperial family and that country generally will have some unseen fatality befall it because of the introduction of the railroads.

It is but natural, therefore, that so benighted a people should attribute their emperor's mother-in-law's illness to railroads, for however a Western people may look upon a mother-in-law's sickness, in China it is considered by no means a blessing.

And now, Mr. Editor, I hope that I have made plain the points I wished to enlighten you on; these are, that the foolish news which appeared in your world's medical newspaper did not refer to Japan, but to China, and that the "simple logic" which you cite of railroads being the cause of human illness, did not emanate from the ingenious mind of a Japanese priest of Buddha (learned in Sanscrit lore from which are derived your European languages) but from that of a prententious Chinese Taouist.

Very respectfully,

M. Tsuchiya.

New York Correspondent Tokyo Nichi-nichi Shumbun (Tokyo Daily News).

[We make the corrections with pleasure, at the same time assuring our readers that the so-called "Professor of Wind and Water" has properly vindicated his title to at least one of his specialties.—Ed.]

DENTISTS.

To the Editor of the Medical Record.

Sir: The article "Defects in the Dentist," published in the issue of the Medical Record of January 27th, in my opinion maligns too many of the dental profession of to-day. I have no doubt there are defects in the methods of the best of dental practitioners—strange if there were not—likewise has the medical profession some in it who are defective in knowledge, or, if they know, do not make use of all the recent discoveries in daily practice; but why condemn the whole for the sins of a few? That the dental profession does not possess the knowledge wherewith to prevent caries of the teeth is not because they do not desire to. "The mouth is a rich culture-ground for microbes," and despite all the care the patients can possibly give the mouth, the microbes are present, and do their work faithfully and without ceasing.

You do not know, evidently, how carefully most dentists endeavor to render thoroughly aseptic themselves and their instruments, especially after an operation where the least suspicion of specific disease exists. You evidently do not know that many, if not most, of them have their special appliances, for heating water to 212° F. of heat, and their solutions of carbolic acid and bichloride of mercury in constant and intelligent use.

The dental literature is so full of all the modern theories concerning septic and antiseptic conditions, as applied to the oral cavity, that he who runs may read, and as for recognizing either the primary or tertiary stage of syphilis, there are many who would know at a glance all that anyone could know without the aid of the history of the case or a microscopist.

To render the mouth thoroughly aseptic is impossible

except for a very limited time, if at all, and he who would keep it so always must of necessity do little else. The profession recognizes its inability to successfully cope with many of the pathological conditions that exist in the human mouth, and are at work constantly to not only repair the injuries done, but to devise means whereby they can be prevented. They are making rapid progress, and are able to prevent some and materially mitigate the action of others. Sometime ago a filling material was much used that under certain conditions of the mouth had peculiar preservative properties, and by some enthusiasts was said to be sure death to any microbe that might be venturesome enough to attempt to skate across its polished surface.

The profession has many members who are able and intelligent workers, and who give freely of their knowledge; and it is readily absorbed by a large class of workers "at the chair." It is used intelligently in daily practice, and great benefit is being derived therefrom by the public. The clinics of the various dental societies are replete with specimens of all stages of diseased conditions of interest and of value to the dentist.

"Let some one devise a way of making the gums aseptic and prevent caries," and who will not call him blessed? Let some one devise a way to prevent tuberculosis, and who among us would not call him the greatest benefactor mankind has ever known save Jesus Christ? So long as there exists the law of heredity, just so long will we find the various predispositions and idiosyncrasies, and the least of these is not a carious diathesis of the teeth.

WILLIAM E. TRUEX, D.D.S.

FREEHOLD, N. J.

AMPUTATION AT THE HIP-JOINT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a letter to the MEDICAL RECORD of February 10th, Dr. John A. Wyeth says, "I have implicit faith in the spirit of fairness which prevails in our profession, and believe that whatever credit I am entitled to for devising and developing the 'Bloodless Amputation at the Hip,' will be accorded me." I fully agree with him in this, and feel sure he will be accorded due credit for developing the method under discussion and for calling the attention of the profession to it; but still, believing in this spirit of fairness, I am equally sure the credit for having originated the method will not be given to him, but to Volkmann.

No one can deny that Volkmann gave to modern surgery a method of amputation at the hip-joint very similar to Wyeth's. That the method published by Wyeth should differ from it in some minor details is only natural. If it was devised without any knowledge of Volkmann's method it would do so accidentally; if it was taken from Volkmann's method it would be modified purposely.

Dr. Wyeth says a discussion of the subject, whether or not the Wyeth method of hip amputation be properly named, has very little personal interest to him. This seems strange coming from a man who is so interested in what he claims to be his method, that he appends a column of endorsements and recommendations to an article upon that subject, as he did in the *Medical News* of December 9, 1893, and from a man who becomes as agitated in the very discussion which has no interest to him as Dr. Wyeth evidently did, to judge from the tone of his communication.

In that article Dr. Wyeth speaks sarcastically of surgical acumen, well-informed surgeons, etc., but does not explain why he failed to find "any mention or description of any such operation" in the works of König and Heinicke, which he claims to have searched. Verily, "there are none as blind as those who will not see."

Dr. Wyeth has presented his case. I will present mine. Dr. Brashear originates a method in 1806. It becomes so completely lost that even Dr. Wyeth does not know of its existence. Volkmann devises the same, or a very similar, method seventy-five years afterward. His method is published in standard surgical text-books and becomes known to well-informed surgeons as Volkmann's method. A very few years later Dr. Wyeth publishes a very like method. His attention is called to the similarity of the methods. He denies that Volkmann originated such a method, and declares he cannot find "any mention or description of any such operation" in certain works. It is proven that a description of such a method is contained in all the works he cites which are at the writer's command, as well as in others he does not mention. Then Dr. Wyeth, becoming agitated, ceases argument and engages in sarcasm. In his agitation, however, he becomes inconsistent. He says, "The only real point of similarity is that the lower extremity is removed at the hip-joint in both procedures." In the very next sentence of the same paragraph he says his first operation "bears a close resemblance" to Volkmann's. Does not his improved operation bear a close resemblance to his first? Are they not founded upon the same principle? If his first operation resembles Volkmann's, does not also the improved? Does not Dr. Wyeth himself virtually admit his method to be an intentional or unintentional modification of Volkmann's?

In the paragraph above referred to he acknowledges his indebtedness to the writer for having cited him to "the operation advised (but never performed) by Volkmann in 1886." Why did he jump at the conclusion that Volkmann had never performed the operation up to that time? I made no such statement, neither is that the fact of the case. I am perfectly willing to permit the members of the profession who have heard the evidence to sit upon the jury, and to abide by their verdict, feeling sure that sarcasm and abuse cannot triumph over indisputable evidence—the description of Volkmann's method in the works cited by me in my communication of January 27th, and Dr. Wyeth's own admission that his first operation bears a close resemblance to it.

Pathology as She is Wrote.—The following, under the caption of "Snakes in the Blood," is a reporter's idea of Filaria Sanguinis Hominis: "A discourse on the disease of which King Herod died entertained the doctors who gathered at the Section on General Medicine. It was read by Dr. G. Laussure, of Charleston, S.C. In the disease described, little white snakes get into the blood and wriggle about until the patient dies. Several of these were exhibited. The doctors call the disease Filaris Hominis Sanquinis, and it occurs at the present time only rarely. The snakes, which are long, white substances, retire to the secluded organs of the body in the day when the subject is moving about, but come into the veins and arteries at night when he is sleeping."

NOTES ON THE PHYSIOLOGICAL ACTION OF OZONE PREPARATIONS.[1]

BY W. GILMAN THOMPSON, M.D.,

PROFESSOR OF PHYSIOLOGY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

My attention has been called to the physiological action of hydrogen peroxide and ozone by the prominence given of late in medical literature to the clinical use of active oxidizing agents, and by the increasing number of alleged ozonizing nostrums which are offered to a credulous public. The experiments here recorded I have recently performed in the Loomis Laboratory, with the object of determining the maximum effect produced upon certain bodily functions, and upon the blood, by the injection in various ways of such preparations. The ingenuity of the manufacturers is exhibited in the coining of such names as aquozone, bi-ozone, pyozone, ozone-inhalers, electrozone, liquid oxygen, glycozone, therapol, etc., which agents, though they differ somewhat in process of making, all have the same object in view when given internally, namely to increase the quantity of oxygen carried by the blood, and to promote greater activity of tissue oxidation. We know that the hæmoglobin of the blood is so nearly saturated with oxygen in ordinary respiration that it is practically impossible to cause it to convey any more, and further, that under conditions of atmospheric pressure compatible with life, the blood plasma cannot be made to absorb from the inspired air an excessive quantity of oxygen even though that air consist wholly of oxygen.

We may state on *à priori* grounds: First, that it certainly is not possible to introduce additional oxygen more readily into the blood by way of the alimentary canal than through the lungs. Secondly, the total quantity of oxygen which can be swallowed in fluid of any kind must always bear a very minute proportion to the amount inhaled in a few additional respirations. Thirdly, should we, for argument's sake, admit that a very little nascent oxygen or ozone is of more value to the tissues than the ordinary respiratory oxygen, does it not immediately exhaust its nascent energy upon the alimentary epithelium, or, if it could enter the blood, upon that tissue itself, leaving none free for general tissue oxidation?

The very great value of hydrogen peroxide and of some other ozonizing preparations as local antiseptics and cleansing agents is freely admitted. It is abundantly proven by constant clinical experience and record.

The problem under discussion merely concerns the possibility of getting ozone into the body by its internal administration, and its immediate effect upon the tissues. The animals were all anæsthetized throughout the experiments.

EXPERIMENT 1.—A dog weighing 20 pounds was etherized and a close fitting tracheal cannula was introduced which could be completely closed by a stop cock. On suddenly closing the cock, the animal continued breathing (using the residual or reserve air in the lungs) for a minute and a half. Air was then allowed to enter freely, and the experiment was repeated several times to establish this period (one minute and a half), as the normal one for cessation of respiratory effort. One pint of fresh, fifteen volumes per cent. hydrogen peroxide (made for me by a reliable firm), was then injected slowly through a cannula into the right femoral vein. The injection was completed in twenty minutes. Five minutes after the injection was commenced the tracheal cock was again turned, and this time respiration did not cease for two minutes. The blood throughout the arterial system immediately became absolutely black. In ten minutes respiration did not cease after closing the cock until four and a half minutes had elapsed, and this remained the average time during the whole experiment. Meanwhile a small quantity of arterial blood was withdrawn and found to coagulate in about half the usual time, and with much greater firmness than the ordinary dog's blood-clot. Examined microscopically the corpuscles were all found crenated, or greatly shrivelled and disorganized, and a large quantity of free pigment was contained in the plasma. The animal lived for two hours under ether, the respirations appearing normal in depth, but slow, while the cannula remained open. The dog was then killed, although still in good condition. All the viscera appeared as absolutely blanched as if the blood had been washed out by normal salt solution.

This experiment is of great interest in demonstrating that an agent which thoroughly disorganizes the blood, may yet convey enough oxygen to the respiratory centre to maintain the normal respiratory rhythm and even to prolong the period of rhythmic respiratory effort when the air-supply is cut short.

EXPERIMENT 2.—A healthy young bull-dog, weighing 22 pounds, was etherized and a tracheal cannula with a stop cock was inserted as in Experiment 1. It was ascertained by repeated trials that after cutting off the air-supply, normal respiration ceased in two minutes. One ounce was then injected slowly into the left femoral vein of a sample of hydrogen peroxide (made for sale and not prepared especially for me, as was the peroxide used in Experiment 1). This preparation is advertised as "absolutely harmless for internal use." The dog immediately stopped breathing and died. Considerable free gas appeared in the blood-vessels, and the blood from the carotid artery was almost black. The omental vessels were quite empty, while those of the intestinal wall were greatly congested with very dark blood, blacker than ordinary venous blood. The red blood-corpuscles everywhere were crenated or disintegrated. The experiment illustrates the variability of the peroxide preparations, this sample being much more potent and fatal (possibly from acidity) than the one used in Experiment 1.

EXPERIMENT 3.—Young dog, weight 15 pounds, etherized. Conditions identical with Experiment 2. Half an ounce of the same sample of peroxide used in Experiment 2 was injected in the right femoral vein, and death ensued in two minutes, all the blood being black and disorganized.

EXPERIMENT 4.—Mongrel dog. Weight 19 pounds, etherized. Conditions identical with Experiments 1, 2, and 3. Before injection, on closing stopcock, breathing ceased in two minutes. Five and a half ounces of fresh hydrogen peroxide (identical with that used in Experiment 1), were injected at intervals during one hour, and on closing the cock the respiratory movements continued for four and a half minutes. During the injection muscular tremors and convulsive movements ensued. During the experiment the rate of respiration fell from

[1] A paper presented before the American Physiological Society, December 28, 1893.

72 to 24 and the pulse rate rose from 180 to 220. The animal died at the expiration of one hour. The omentum was blanched, the liver and spleen were engorged and deeply pigmented, the kidneys anæmic. The peripheral veins were almost empty. The heart was dilated and full of very dark uncoagulated blood. The red blood-corpuscles were disintegrated.

Experiment 5.—Mongrel dog, weight 27 pounds; etherized. Conditions same as in Experiments 1, 2, 3, and 4. After closing the tracheal cannula breathing ceased in one minute and a half. Seven and a half ounces of another sample of fresh hydrogen peroxide were injected slowly during the course of an hour in the left femoral vein. Frequent convulsions occurred, many of which were excited by slight external stimulation, movement of the legs, etc. Respiratory movements continued for five minutes after closure of the cannula. The animal was kept alive under ether for two hours, and during this time the rate of respiration fell gradually from 70 to 30, and the pulse rose from 180 to 200. Examination of the viscera and blood showed the same conditions described in Experiment 3. A stream of oxygen gas, passed through the black arterial blood, failed to restore its color, as it usually does with venous blood.

Experiment 6.—Dog, weight 17 pounds, etherized. Conditions same as in Experiment 1. On closing stopcock respiratory movements ceased in three minutes. Seven and a half ounces of peroxide solution, fifteen volumes per cent., were then slowly injected into the femoral vein during a period of forty minutes. In this time respiration fell from 96 to 72 and the pulse rose from 180 to 204. On closing the cock respiratory movement ceased in three and a half minutes. The shed blood began to coagulate in one minute, and set firmly in six minutes.

In all the above six experiments the peroxide was used in the same strength, fifteen per cent. (*i.e.*, each pint of the solution contained fifteen pints of ozone) and was slowly injected in considerable quantity directly into the circulation. Two of the animals died at once. In both these the same preparation was used, which was obtained in open market. In the four other dogs a preparation was used which was furnished to me by the manufacturers expressly for experimental research. In all these animals there was decided effect upon respiration, the rate being several times reduced by fully one half, and the duration of respiratory efforts, when the air-supply was cut off, being at times more than doubled. Moreover, respiration and circulation both continued for from one to two hours in spite of a condition of disorganization of the blood itself which must have immediately destroyed the oxygen carrying power of the red discs. The conclusion would seem to be that the peroxide furnished sufficient oxygen to the respiratory centre and to the tissues to maintain their functional activity after the blood itself had become useless. The duration of life with the maintenance of considerable vigor, far exceeds any results which I have been able to attain by replacing the blood of the dog by normal salt solution (injected in a similar quantity in a vein to replace blood drawn from an artery).

Experiment 7.—Young dog, weight 14 pounds, etherized. Artificial dyspnœa produced by section of both vagi. Respiration fell from 75 to 30, deep and labored. One ounce of peroxide solution, fifteen volumes per cent., was injected into the left femoral vein in order to ascertain if the vagus dyspnœa was relieved. No improvement in the breathing resulted and the animal soon died.

Experiment 8.—A vigorous young bull dog, weighing 25 pounds, was etherized and the stomach was exposed and thoroughly washed out from the cardiac end. The pyloric end was then ligated and three ounces of fresh hydrogen peroxide, fifteen volumes per cent., were injected into the stomach. In five minutes minute bubbles of gas were visible, rapidly flowing through the gastric blood-vessels. Their appearance was followed by extreme congestion of the gastric veins, accompanied by intense ecchymosis. The stomach itself became greatly distended by gas. An hour and a quarter after injection of the peroxide the animal, though in good general condition, was killed. It was found that one ounce of the fluid had been absorbed, but the mucous membrane of the stomach was reduced to a pulp of disorganized epithelial cells and granular detritus. The entire organ was very dark and congested.

Experiment 9.—Dog, terrier, weight 20 pounds, etherized. Isolated loop of small intestine ten inches long isolated by two ligatures; after thoroughly washing its mucous surface, one ounce of hydrogen peroxide, fifteen volumes per cent. solution (a new preparation sent as sample for medical use and warranted "harmless"), was injected with a rubber syringe into the lumen of the loop. In two minutes bubbles of gas were seen in the vessels of the omentum, which soon filled them and replaced all the blood, leaving the omentum completely blanched. At the same time the relaxed intestine swelled and became as tight as a drum-head. In five minutes the bubbles of gas began to exude on the omental surface of the gut, so as to cover it over with a thick white froth. In ten minutes the gut ruptured from the pressure of the gas within, which escaped with a loud report. On examining the inner surface, the mucous membrane was found reduced to a pulp, which was readily scraped off with the finger-nail. In places the intestinal wall was eaten through the muscular layer as well.

Experiment 10.—In the same animal a fresh loop of intestine eight inches long was similarly isolated by ligatures after cleansing, and an ounce of a 1 to 100 dilution of the fifteen volumes per cent. solution was injected. The omental vessels soon showed bubbles of gas, although they were less abundant than in the previous experiment, and a few bubbles made their way through the thinned and stretched intestinal wall to its external surface, where they were plainly seen. The specimens of peroxide used in this and the two preceding experiments (8 and 9) gave a very strongly acid reaction with litmus.

The last three experiments (8, 9, and 10) demonstrate that hydrogen peroxide, if given in excessive quantity, enters the blood-vessels from the stomach and intestine, but it disorganizes the mucous lining with evolution of free gas, which passes in visible bubbles into the smaller vessels. In the intestine the same thing occurs even when the solution is diluted 1 to 100 in water.

Experiment 11.—Small dog, weight 18 pounds, etherized. Conditions same as in previous experiment; three ounces fresh hydrogen peroxide injected into stomach. Immediately bubbles of gas appeared in vessels of gastric wall and spleen, and other abdominal vessels became very dark and engorged. In three-quarters of an hour, two ounces more were injected, and the respiration gradually fell from 60 at the beginning of the operation to 30, but it remained deep and regular. The pulse, on the contrary, rose from 160 to 245 after two ounces more were given, making seven ounces in all. It also became very weak and irregular. After one hour the animal grew so feeble that it was killed. The stomach wall was œdematous, and the mucous lining was softened and covered with a pulpy mass of disintegrated cells and mucus. The red blood-discs everywhere were crenated and greatly shrivelled, and there was free pigment in the plasma, but none in the urine; three and a half ounces of the peroxide were found to have been absorbed during the hour.

The effects of ozone in considerable quantity in the strength of fifteen volumes per cent., acting on mucous membranes and directly upon the blood, has been shown by the four preceding experiments (8, 9, 10, and 11) to be very destructive and hazardous. It is advertised of one of the stronger preparations of hydrogen peroxide that it may be swallowed with impunity in half-pound doses. If this be true it cannot contain the percentage of ozone which is claimed for it. Of another preparation of hydrogen peroxide which I know to be extensively prescribed, and a sample of which I experimented with, it is stated that "taken in excess it will do no harm, since the sys-

tem will appropriate only what it can use at the time," that "it is safer to give too much than too little," and that "an adult man, as an experiment, imbibed one pint of a fifteen volumes solution at a single dose without experiencing a single untoward symptom or any notable discomfort." This may have been due to the extremely rapid deterioration which a stale or uncorked bottle of hydrogen peroxide undergoes.

EXPERIMENT 12.—A bat's wing was exposed on the microscopic stage, and the smaller blood-vessels were brought into view with a low-power lens. The epithelium was then denuded in the neighborhood of the visible vessels, but not immediately over them. A drop of peroxide solution of fifteen volumes per cent. was placed upon the denuded area, and bubbles of free gas were immediately seen circulating in the vessels among the blood-corpuscles. The latter became greatly impeded in their movement, and in two or three minutes many grew shrivelled and disintegrated. Observations with microscopic fresh human blood demonstrated the same destructive action. Added to blood in the proportion of 1 part peroxide (fifteen volumes per cent.) to 16 of blood, violent effervescence ensues.

EXPERIMENT 13.—A different solution of peroxide from any previously used was obtained from a sample sold for medical use. It was found that a solution of fifteen volumes per cent., and also the same solution diluted 1 to 100 in water, immediately disorganized fresh arterial dog's blood, with lively effervescence and production of a deep black color. The shed blood still coagulated, beginning to "set" in one minute, and in five minutes became sufficiently firm to allow of inverting the glass cup in which it was contained. (This is about the ordinary time for coagulation of venous dog's blood.) The clot was fairly firm, despite the fact that it contained numerous gas-bubbles.

EXPERIMENT 14.—A solution of hydrogen peroxide, fourteen volumes per cent., was obtained from a bottle from which a druggist had been dispensing it for internal use and added to fresh arterial dog's blood. The reactions were identical with those described in the previous experiment (13). The solution itself gave a strongly acid reaction with litmus.

EXPERIMENT 15.—The preparations used in Experiments 13 and 14 were added to fresh dog's bile, which immediately changed from a dark red-brown hue to a vivid light green, showing decided oxidation.

EXPERIMENT 16.—Dog, weight 20 pounds, etherized. Thirteen ounces of a solution, advertised to contain ozone in considerable amount, were injected into the femoral vein. No decided effect upon either pulse or respiration. The animal lived in good health for ten days. This preparation was certainly not as strong in ozone as it was represented to be.

The observations of enthusiasts for the medicinal use of ozone and those of most physiologists seem, unfortunately, at variance. Thus, we are confidently told by the former that the internal use of hydrogen peroxide "seems to supply oxygen to the blood and so act vicariously to a small extent for the purpose of respiration,"[1] and "daily inhalations of ozone increase the quantity of oxyhæmoglobin in the blood from one to four per cent. in a short time."[2]

Dr. Lee[3] says: "For internal treatment my experience taught me that the medicinal peroxide, given in cupful doses of the strength of four per cent., or even much stronger, was a better antiseptic than any other drug known in the treatment of cholera." He also recommends, in this disease, irrigation of the intestine "with one or two gallons of warm water containing four per cent. of peroxide of hydrogen."

Dr. William J. Morton refers to the successful internal use of ozone in the MEDICAL RECORD, June 10, 1893, p. 733.

[1] R. W. Richardson: Paper read before Medical Society of London, March 23, 1891.
[2] A. Caillé: MEDICAL RECORD, May 14, 1892, p. 553.
[3] Clinical Review, Chicago, 1893.

One writer (Wallian) goes so far as to claim from its internal use, the cure of sterility (!). It is clearly unsafe to give large internal doses of strong hydrogen peroxide. In small doses of an ounce or two, or in diluted strength of say five or ten volumes per cent., the quantity of ozone imbibed must be inconsiderable. There is some dispute as to the *modus operandi* of hydrogen peroxide, but it is generally claimed that on coming in contact with a mucous membrane the peroxide is split up into free oxygen (or ozone) which is absorbed, leaving water behind. If it be oxygen (O_2) which is liberated, surely this can be of no more value than so much air in the stomach, where it is certainly out of place, for although simple oxygen (O_2) may be absorbed from the stomach wall, far more of it can be got into the blood at any time by taking two or three additional respirations of pure air. Simple oxygen, however, could not disorganize the blood and tissues, and affect the bile as the gas in question does. If it be really nascent oxygen (O_1) or ozone (O_3) which is liberated, what must of necessity occur? We know that "ozone" is the most difficult to preserve of all gases, it "explodes" back to simple oxygen so readily.[1]

It cannot exist an instant in the presence of any oxidizable substance or of any organic cells without combining with their protoplasm. When swallowed, therefore, it is immediately decomposed by the mucus and lining cells of the mouth, œsophagus, and stomach. That oxygen gas of some sort, whether simple nascent oxygen or ozone, does enter the blood-vessels liberated from solution as a result of this sudden molecular dissociation, has received abundant ocular demonstration in the foregoing experiments (8, 9, 10, and 11). If this gas on entering the blood be simple O_2 it is of no more value to the system than if it entered in the usual way through the lungs. But from its disorganizing effect on the corpuscles it must be stronger than O_2. If it be ozone, O_3, it immediately decomposes the blood, at first locally, and if it be liberated in large enough amount, then all the blood in the body is disorganized. Bunge[2] says, "*a priori*, there is no point in trying to trace ozone in the body. Many litres of oxygen containing ozone might be pumped into the blood and yet we could not pump out a single molecule of ozone."

If the absorbed gas is in small amount, it is soon exhausted locally on the blood in the nearest vessels, and is never carried far in the circulation (certainly not to the lungs to destroy tubercle bacilli, or to the liver to modify the glycogenic function which has been claimed for it). If absorbed in very large amount (or put directly into the blood as in the experiments above recorded) it destroys more and more blood, and if carried in the circulation it eventually reaches remote tissues. In order to affect them in the slightest degree, it has destroyed permanently all the blood en route. The same line of reasoning applies to the inhalation of ozone. There are few topics in therapeutics about which so much fallacy has been produced as regarding the oxidation of the general body tissues by "ozonizing agents," and, in fact, by the use of pure oxygen inhalation, except where it is of undoubted value in certain forms of dyspnœa.[3]

Our knowledge of the ultimate oxidations of the tissues, and, in fact, of the exact form and method of liberation of the oxygen carried by the hæmoglobin of the red blood-corpuscles is still under discussion. Foster,[4] after considering the peculiar nature of the combination of oxygen with hæmoglobin, says: "It has been supposed by some that the oxygen thus associated with hæmoglobin is in the condition known as ozone, but the arguments urged in support of this view are inconclusive." Schönbein, who discovered ozone, suggested this possibility. Free oxygen cannot be found in protoplasm or tissue at any given moment, for while there seems lit-

tle room for doubt that in some of the digestive and tissue chemical changes in the body nascent oxygen (O) is liberated, it is immediately re-combined, and not conveyed for any distance in the circulation to affect remote parts of the system. Halliburton[1] says: "Thus, in the lactic and alcoholic fermentation, and in putrefaction, there is a liberation of hydrogen, and this nascent hydrogen combines with an atom of oxygen from ordinary oxygen, O_2, to form water ($H_2 + O_2 = H_2O + O$). The nascent oxygen (O) thus liberated, oxidizes any oxidizable substance present, or it may unite with hydrogen to form water or oxygen to form ozone (O_3). It is probable that some of the changes occurring during the nutrition of living cells are similar to these fermentations." Hoppe Seyler and Baumis[2] have previously advanced similar views. MacMunn[3] prepared a substance closely resembling the normal pigment of the urine (urobilin), from the action of hydrogen peroxide on acid hæmatin. Bunge[4] argues ably that "the third oxygen atom in the molecule (O_3), which causes the powerful oxidations, can have no other property than that of nascent oxygen" (O), and "ozone is never formed in the body though we meet with energetic processes of oxidation." Neither is it of avail to try to get it into the body, where it can only do more harm than good.

Bunge[5] further says, in speaking of the normal rapid oxidation of food stuffs which takes place in our tissues. "We must, however, not forget that the participation of active oxygen in the process is at present only an hypothesis and that the facts are capable of another explanation."

This view is also held by Pflüger. No substance exists in the blood capable of acting as an ozone carrier, to convey an unaltered molecule of ozone from one part of the system to another. Brunton,[6] in referring to ozone, states that "it has a curious action upon albumin (in preventing its coagulation) and decomposes blood. As might be expected, it is exceedingly poisonous to low animals and is fatal also to the higher animals."

Its effect appears to be due, in great measure, to its having such a powerful irritant and even destructive effect on the albuminous tissues of the respiratory passages, that it causes reflex depression of the heart and interferes with the ordinary respiration in the lungs. It thus diminishes instead of increasing oxidation.

Rice, in reporting some favorable results from the use of ozone inhalations, says that even when dilute, it produces "mild smarting of the nose lasting for several hours," with "increased mucous secretion lasting eight to ten hours," and congestion of the nasal mucous membrane. Some patients acquire headache from its use, and he refers to one instance of "aphonic laryngitis" caused by the inhalations. These effects certainly show that it should be employed very cautiously and properly diluted.

Jacobi[7] calls attention to the injurious action of peroxide of hydrogen in destroying epithelium when employed too vigorously in diphtheria.

Sonntag,[8] after elaborate investigations, declares ozone to be useless even as a disinfectant.

Until the problems of tissue oxidation are more definitely formulated, it is well to be very cautious in claiming phenomenal nutritive or healing powers for an agent which must of necessity act deleteriously upon the blood before it can reach the tissues. I have observed the effect of the internal administration of some of these "ozonizing agents" in various cases, especially of phthisis, and am convinced that whatever benefit they may be said to possess, when given in reasonable dosage, is solely from local antiseptic or anti-fermentative action.

Conclusions respecting the effect of ozonizing agents when given by the stomach or injected directly into the intestine or the blood:

1. When injected in the circulation in full strength, *i.e.*, fifteen volumes per cent., they have a very destructive action upon the blood, thereby ultimately having the effect of reducing rather than of oxidizing agents for the tissues.

2. Acting through the stomach or intestine, they may similarly affect the blood, and in addition they destroy the gastric and intestinal mucous membrane.

3. Given in medicinal doses by the stomach, their only benefit, if any, consists purely in their local action in the alimentary canal, in possibly preventing abnormal fermentations.

4. If so used, care should be exercised, owing to the great variability in strength of different preparations.

5. Ozone is of no real value to the tissues, whether inhaled or drunk in fluid preparations, and it may be exceedingly harmful.

CONTEMPORARY UNI BILATERAL STETHOKYRTOGRAPHICAL EXAMINATIONS.[1]

By RICH. HOGNER, M.D.,
BOSTON, MASS.

Measurements of the chest have been taken to considerable extent by different examiners for scientific and practical purposes, both in long series to collect material, etc., and in single cases to confirm a diagnosis and—as is now quite universal—to make medical examinations for life insurances. Every method of measurements formerly employed has, however, its weak point, either being too complicated, impractical, inaccurate, or not capable of taking unilateral registerings simultaneously on both sides.

The ideal chest-measuring apparatus is one that is capable of giving results for both sides simultaneously, for each one separately (contemporary uni-bilateral); which can be placed anywhere whatever on the thorax, is easily operated, and which, moreover, is accurate.

The stethokyrtograph in question is, even in some purely scientific respects, incomplete, but is sufficient for all practical purposes.

The properties of the apparatus and the rules for its use have been deducted from two hundred and three cases, including about sixteen hundred measurements (ranging from two measurements in one séance to eighty four in fifteen séances in fourteen days), after which other persons were added to the cases previously mentioned—in all, six hundred and thirty-six persons. The result of the measurements, being formulated into fourteen tables, form the basis of the following remarks. These measurements have, moreover, been daily corroborated, so that faith in the apparatus rests upon nearly four thousand measurements made on about twelve hundred persons.

The Stethokyrtograph.—The stethokyrtograph consists of a double slot of metal (see illustrations) in which two self registering cylinders of equal weight run side by side by means of cords and metal disks, which can be adjusted on suitable places around the thorax; also of a neck-band in which the apparatus hangs over the sternum. (See Fig. 1.)

The double slot is 145 mm. long, 38 mm. broad (each slot 18 mm., besides the thickness of the partition); at the upper end provided with a hook to attach it to the neck-band, also with a pair of fixed disks to guide the cords from the perpendicular to a more or less horizontal position. At the foot of the apparatus is a small catch to hold the registering paper underneath the slots in a firm position. (See Fig. 2.)

The registering paper is double, consisting of an underlayer of thick, ordinary drawing-paper, and also of an upper layer of thin, white tissue-paper, the latter of

[1] The following article is only an extract of several chapters from a longer work. For that part, "saltus in demonstrando," intended to be amplified in a succeeding treatise, especial indulgence is craved.

which is found to be especially sensitive to the black lead which is employed here. The thicker paper is used only to stiffen the tissue-paper and keep it in place and

Fig. 1.

smoothly spread out, and to secure this result the tissue-paper is folded over the upper and lower ends of the

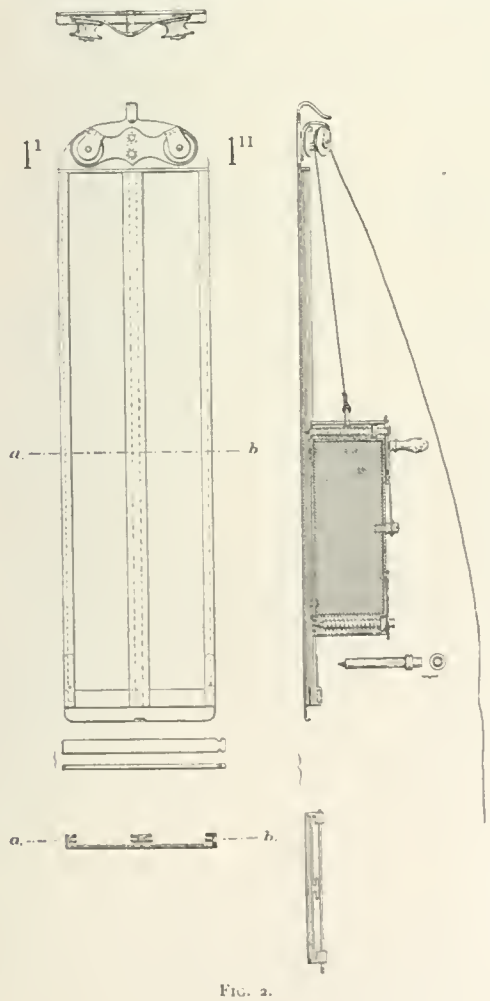

Fig. 2.

thicker paper, and is thus pushed to the upper end of the slots, after which it is fixed, together with the thicker paper, with the finger-nail or a knife-blade pressing it under the catch at the lower edge of the apparatus. The thicker paper can be used for a long time, whereas the tissue-paper must be renewed for every new examination made. The tissue paper is of sufficient length to receive registrations of the difference in two series of deep inspirations and expirations, plus one or two shorter ones; adequate, therefore, for the examination of one person. (See Fig. 5, Case XXXIX.)

The cylinders are 58 mm. long, 20 mm. in diameter, filled with lead; each is 175 grammes in weight, and in the upper and lower ends they are supplied with registering pencil, also each cylinder moves in its own slot on four feet or projections. (See Fig. 3.)

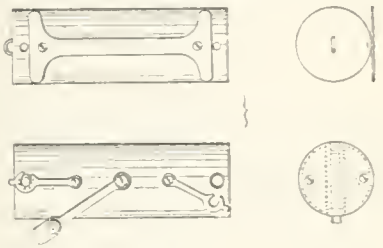

Fig. 3.

The pencils, one at each end of the cylinders (thus four in all), are of black lead (Faber W. 6), set in a holder which can be raised or lowered by means of a spring and lever, according as one wishes the pencil to be in motion or at rest. (See Fig. 2.)

In the upper ends of the cylinders the running cords are fastened. These consist each of silk threads 55 ctm. long, overspun with metal (so called gimp No. 5), which, after a little use, run easily and evenly. The "gimps" are joined to round leather strings, the thickness of a darning-needle, and 50 ctm. long, which, held together on the patient's back, form a chain around the same. The leather strings are only a sort of grasping medium, while the gimps are too fine and smooth to be held comfortably together and in place while the cylinders are in motion.

The disks over which the gimps glide are, besides the above-mentioned (1^{I} and 1^{II} sitting firmly at the upper end of the slot), twelve detached and movable ones (2^{I} and 2^{II}, 3^{I} and 3^{II}, etc.), designed to be placed around the body so the gimp will run freely on them without hurting the front or sides of the chest. On the back—the least movable part of the thorax—the leather strings and the gimps are allowed to rest directly on the skin. The disks have a radius of 3.5 mm., and sit generally so low on their axis that they move evenly and freely—the stationary ones from the apparatus, the movable ones from the large foot—20 by 20 mm.—which is more or less bent according to the form of the human body. Only the 2^{I} and 2^{II}, 3^{I} and 3^{II} movable disks, nearest the apparatus, which, in measuring the upper half of the chest are placed on the *regio subclavicularis*, are more elevated on the axis (6

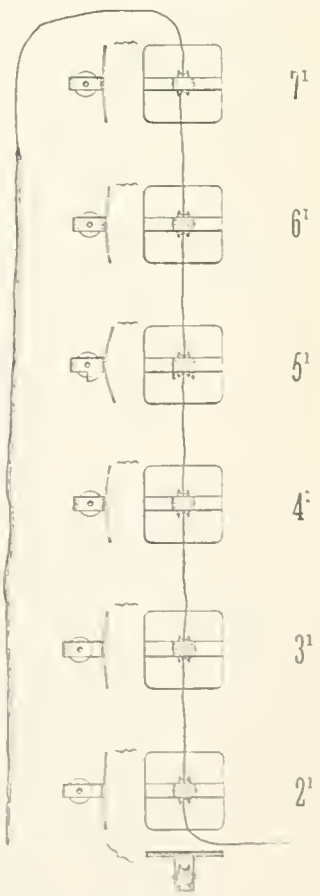

Fig. 4.

to 7 mm.) (see Fig. 4), so the gimp can be somewhat higher on them, or, at least, as high from the thorax as when they leave the disks fastened to the double slot. Were this not the case, the subclavicular disks would not lie close to the body, perhaps only swing in the air and not pass along the gimp, and then undoubtedly would not convey the right impression to the gimps and cylinders of the real dilatation in their respective regions. Of the remaining disks, the next, 4^{I} and 4^{II}, 5^{I} and 5^{II} are designed for the forward axillary region, the 6^{I} and 6^{II}, 7^{I} and 7^{II} last for the posterior, and the latter "anterior axillary disk" 5^{I} and 5^{II} has a little projection which keeps the neighboring disk from coming so near that the free motions are disturbed. The movable disks are as narrow as possible, and yet broad enough so that the gimps shall not be pressed into the rather deep groove; while the stationary disks are somewhat broader, with somewhat more shallow grooves; while the gimp, in order to change its direction from vertical to horizontal, needs greater space here. It is of the greatest importance that the stationary disks should have the proper position in relation to the double slot, so that the gimps will not scrape against any edge or corner, and thus their gliding motion be hindered.

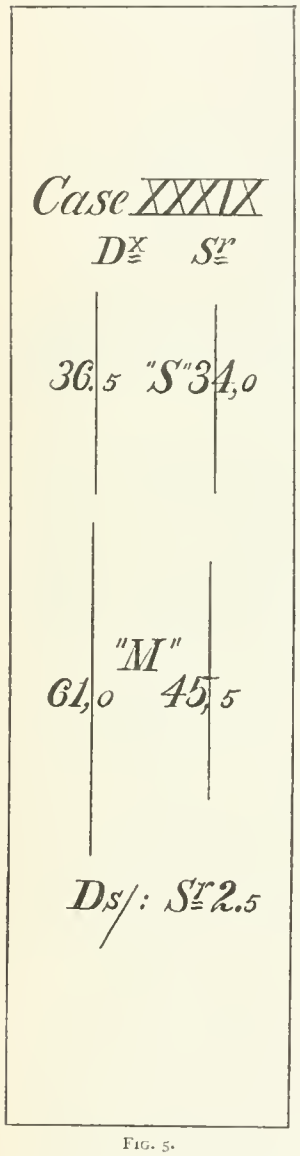

Fig. 5.

The neck-band is provided with a hook and rings for fastening it around necks of different size; also with a little linked chain in which the apparatus can be fastened higher up on the upper portion of the chest or lower down in the mammillary region without it being necessary to remove the apparatus.

To the apparatus belongs a little metal pin, large enough to push out the pencil, and which is fastened in a little wooden bar which is used partly for keeping the apparatus lying firmly in its case, and partly, when measuring, as an assistant to the double slot, so that its upper end will rest against the sternum. Finally, there is a tin-plate according to which the paper strips are cut. That the under-side of the double slot is covered with woollen to take away the uncomfortable chill of the metal apparatus, hardly needs mentioning.

The Method of Using the Stethokyrtograph.—After one is assured that the apparatus is in order, that the gimps are not knotted, that the black leads simply write when the lever is in place, and that there is no greater friction than is necessary,[1] the "patient" has to disrobe to the waist. The physician places himself, be he right-handed, on the right side of the patient, finally also far enough forward to be able to see the left shoulder and the part of the chest lying under it during the examination.

The neck-band should be fastened closely around the neck, so the apparatus can come as high up as possible, then command, "hips firm," which preparatory position is modified, however, by holding the hands loosely against the hips (the thumbs always backward), held there almost entirely by the weight of the upper arm, and always in precisely the same bilateral position with the elbows pointed outward and the hands equally bent, dorsally, on both sides. The "patient" should stand firmly, the feet somewhat apart; should not contract the muscles, either in the armpit or elsewhere, also hold the head still, bent forward and downward. "Immovability" is of especial importance. With the movement of the head backward, for instance, the volume of the throat is increased, it seems to dilate and elongate in front, at which the apparatus is simultaneously lifted and a too high result is obtained. When one shoulder is lifted the corresponding side of the chest is more raised, and the result is relatively too high for this side. When the head or the body is turned or the hands moved, the result will be likewise unreliable.

The apparatus is to be hung on the neck-band, generally in the first ring, high enough for the stationary disks to come between or immediately under the collar-bone in the regio interclavicularis, after which the end of the chain is fastened under the neck-band so it cannot hang down in the way. The gimps and disks must be disentangled, if necessary, and be carried backward on each side of the chest, grasped with the left hand, held against the "spina dorsi," and held together rather tightly at the back. The movable disks must now be pushed to their places and are duly adjusted on exactly corresponding points on both sides of the body: 2^{I} and 2^{II}, 3^{I} and 3^{II} disks in front on the chest, in the regio subclavicularis; 4^{I} and 4^{II} immediately in front of the forward fold of the arm-pit with the foot of the 5^{I} and 5^{II} following, the last "anterior arm pit disk" which is placed over or around the most prominent part. (It is in order to hold itself up and keep its place that this latter disk, not only receives its sharply bent feet corresponding to the axillary fold, but also must be pressed close or be held down by the preceding.) 6^{I} and 6^{II} disks on the posterior axillary fold, and the remaining 7^{I} and 7^{II} disks immediately behind it.

The gimps and disks must be set in as straight and unbroken a line as possible, generally, in order to enable the disks to stand in position from the interclavicular fossa downward and backward in a slanting line.

After the disks are firmly in place, the gimps are made even tighter by drawing up the cylinders to the required height, and a glance is cast over the whole to see that the gimps do not touch the skin (except in back); that the disks are placed firmly and in corresponding points; that the muscles are relaxed; that the head is bent down (to keep this in mind it is best for the physician to allow his disengaged hand to rest on the top of the patient's head during the examination); that the position in other respects is the correct one.

If the double slots at the upper end should not lie close to the wall of the chest, caused by the fact that the apparatus is straight while the breastbone is often convex, then a little prop[1] is placed under the lower end of the slot, so that the upper part slants in (which often will not happen till the cylinders have been drawn up more) and comes so near the breastbone that the gimp lies somewhat lower on the stationary than on the nearest movable disk (without which, as already stated, the gimp will not perform its proper functions).

If all is now in order, the levers are attached carefully, so that the cylinders' steady position be not disturbed. (In order to place the upper pencil, grasp the lever between the thumb and fore-finger, the support being on the ring-finger; in order to place the lower pencil, grasp the lever between the ring finger and thumb, the support being on the fore finger), and command the "patient" to breathe quietly and deeply or "as usual," "little deeper,"

[1] The black leads should be pointed at the same time, even if only one be dull, so that they may all be of equal length and pressure.

[1] For the prop the little wooden bar with the metal pin, which belongs to the box, can be used.

etc., according to the examination, also without raising or thrusting forward the shoulders, pulling, jerking, or in any way changing his position. During the deep breathing—"breathe slowly and very deeply"—it is best for the physician to breathe in and out to show his meaning. The patient sees, or more correctly hears, how it should be, and, as a rule, follows, so the examination is soon done. After two or three inspirations and expirations the levers are cast out quickly with a little side-motion of the finger-tips between the grasping points, and the registering pencils have ceased their operations.

The first registration of difference is now acquired on the "subclavicular plane" (s), or more correctly, on the infra-clavicular, axillary, and lower scapular plane, the regions on which the disks have been placed. If room remains on the paper for another examination on the same plane, the cylinders are lowered somewhat and after renewed manipulations a second registration is immediately made. It is most convenient to find the difference during surface breathing (in order to have a starting point, as it were, and to accustom the "patient"), and afterward during very deep breathing. If these two registrations agree as to quality and the breathings have been made according to rule, then the apparatus is moved down and a new registration is made with the lower pencils on the same paper; this latter of the difference between the greatest inspiration and expiration on the mammillary plane (m). If, on the contrary, the first and

* 10 : 6 denotes that the length of the sound made by expiration bears the relation to that of the inspiration, when the breathing is deep and even, of 6 : 10. To decide the comparative time of the sound of in- and expiration the examiner has, while the patient breathed, counted silently to himself and in time with the breathing, for the inspiration, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, etc., as long as any sound could be heard, and then from the beginning of expiration, 1, 2, 3, 4, 5, 6, etc., as long as one can distinctly hear the "real" sound of expiration. In adults the breathing rhythm was always so slow that during inspiration one could count to ten in two or three seconds. † (i) First line refers to examination in regio supra clavicularis. ‡ (ii) Second line refers to examination in regio infra-clavicularis.

§ (iii) Third line refers to examination in regio supra-scapularis.

‖ The sound of respiration feeble, and with "mumble" or "bruits" in the end of expiration in regio infra-clavicularis and supra-scapularis.

¶ Strained Sr. anterior neck muscles (sterno-cleid. mast., scalenus ant., etc.) considerably more than Dr., wherefore Sr. s. is comparatively too high; Ds. : Dx. too great.

second registrations (in "s") have not given a harmonious result, the third registration—"deep breathing"—is made on the same plane (s); after which new paper is placed in the slots and on it one or two new registrations are made on "s," and finally a registration from the mammillary plane (m). That, as a rule, only one registration is made from the latter, while two to four from "s" depends on the fact that the subclavicular plane or lung apex is much more important for diagnosis and prognosis, generally speaking, and that the least errors in position and breathing make themselves much more felt here than in the registration for "m."

The examination is now ended. The apparatus is removed; the "patient" dresses himself while the paper is drawn out; the registering lines are measured in millimetres, and the result is recorded.

Although the written description is long, the examination is in reality very quickly made. With a single glance one sees if everything is "all right," and within a couple of minutes, three or four at the most, one has three double registrations on the paper.

If it should happen that a disk falls down, which could be heard and felt immediately, one has to place it on its foot again, readjust, perhaps lower the gimps on the back, and begin again. But such a prolongation of the examination, after a little practice, is seldom necessary. If the patient has moved the shoulders, contracted the muscles in one side of the neck more than in the other, or not stood still, then, for a correct opinion, a new examination from the beginning must be made, for a little shrug of the shoulders, etc., means much; yes, so much that the diseased lung can predominate on such an occasion and register a difference greater than obtained from the sound one.

If registrations of the "deepest possible" dilation are desired on the same paper on the "s-plane," and also for the "m-plane," and if the measurements are taken immediately after each other, it must be remembered that apnœa after the first breath might lower the dilation after the following ones; that, in other words, apnœa can remain for a time. In such a case the patient is told to speak only a little between the examinations, or for several times to "breathe naturally," so that the stock of breath has time to equalize and the result be the one desired, presupposing, namely, that the breathing was the deepest possible. It should be remembered, however, that with a "deepest possible" respiration the neck muscles, pectoral muscles, and others are contracted and distended to the utmost, making the control over the bilateral respiratory muscles (if contracted evenly, alike, and simultaneously) more difficult, and that the accurate difference in shorter breathing is often of fully as great significance, and often more important in making a just decision of the condition of the lungs, than that in a deeper—"deepest possible"—breathing where the control is not so exact. As a rule, the patient has to breathe deeply, to be sure, just as when "sighing deeply," but not too deeply, so he can hardly refrain from throwing his head backward while inhaling, or fall down from vertigo, and while exhaling puff out so he completely "loses his breath" and gets "black and blue" in the face from the exertion.

Such extravagances seldom occur in real life, and ought, for the judging of the lungs' power, to signify as little as the feverish utterances during an attack of "wandering" signify force, and which could not well be taken as proof of superhuman strength of the sick one, but rather as a sudden concentration of all forces which remain. The supra-maximal breathings have therefore, as a rule, not been used (neither should they be used when the question concerns the investigation of the every-day—not the momentary—condition); only the patient was required to "breathe slowly and very deeply."

From the previously mentioned measurements and tables the following conclusions may be drawn:

With Regard to the Trustworthiness of the Stethokyrtograph in Practice.—It is reliable in its registerings. Several measurements should, as a rule, be taken in the same plane; one with superficial or with medium deep, and always one with deep breathing. It is sufficient to make these measurements in one *séance*, any time whatever of day or night, if only methodically.

Several times it has happened that the instrument corrected the "diagnosis per aures," giving a result contrary to what one would have expected from the foregoing (perhaps somewhat hasty) auscultation, and that in renewed examinations the trustworthiness of the stethokyrtograph has been proved. When the reliability of the apparatus has been challenged, the error lay not with it, but with the examiner, who did not proceed methodically or did not interpret the results correctly, by reason of having overlooked some of the exhibitions (myitis, incipient herpes zoster, siderosis, left-handedness, etc.), which influence the "regularly correct" dilation of the breast.

With Regard to the Condition of the Breathing.—The total, bilateral difference ($\bar{s}$, $\bar{m}$), between inspiration and expiration has not so important an influence in the diagnosis, that is, any that is worth mentioning, as the contemporary, uni-bilateral difference (Ds, Dm), especially the uni-bilateral one in "subclavicular plane" (Ds).

The difference between the dilation of the two lungs in the "subclavicular plane," Ds, has in the group, "sound," and in other groups[1] with changes of equal intensity and extent for both sides—been in uncomplicated cases, of right-handed persons, Sr; left-handed persons, Dx. (More fully explained further on.)

The movements of the halves of the chest during respiration have not been as constant during the periods of breathing as at the final results, with a steady and even advantage for the stronger side. On the contrary, the movements of the cylinders have almost never been regular [not to be compared to the movements of a steam machine which rise and fall with mathematical precision, but most resemble two well-matched draught-horses of similar or dissimilar temperament and strength, or two mountain climbers who began their climbing at the same moment side by side], ex analogia, I think, because with rougher muscular motions an anisochronismus often is noticed in the bilateral movements. With, for example, "jumping over a line," it is difficult to "come down evenly;" it is difficult to take hold evenly with both hands, etc., depending on the fact that the strength, feeling, and innervation of the muscles of both sides are seldom precisely alike. If this applies to some of the voluntary groups, it ought to apply to the rest as well, the muscles of respiration not excepted.

In connection with the above it may be mentioned that often, in observing "complicated" cases, the first result has been different for superficial and for deep breathing, depending on the fact that the diseased muscles of respiration or the less sound lung was able to do its ordinary, regular work with slight exertion and so had "the advantage," but that with more exertion it was otherwise.

Age, height, and sex have no effect on the relation of the lungs to each other. What does effect Ds, on the contrary is, diseases other than infiltration, consumption, etc., especially "siderosis," or all changes in the lungs resulting from inhalation of dust.

Regarding the bilateral differences ($\bar{s}$, $\bar{m}$) between dilation of the chest with deep inspiration and expiration, they seem to vary within considerable limits, to mention for the present only "subclavicular plane," from 14.0 and 19.0 to 103.5 and 104.5 mm (this is the greatest chest dilation that has been met in this plane), in the groups "sound" and "sound with prolongated sound of expi-

[1] The examinations or studies in question begun in a hygienic manner to diagnose and arrest the development of a predisposition to consumption, giving therefore to tuberculosis the place of first importance. This is the reason why the conditions of the lungs—or the persons examined—are included in four principal groups: "Sound," "sound, with prolongated sound of expiration," "infiltration," and "consumption."

ration: " also from 14.0 and 17.0 to 81.0 in the groups " infiltration " and " consumption."

In 84.4 per cent. the difference of inspiration and expiration between the two lungs, Ds, has varied from 1 to 6.5 mm.

A dilation of the chest (s̄) of 70 to 79.5 mm.; yes, one of 60 to 69.5 appears considerably more frequently in men than in women, in spite of the latter's well-known " thorax respiration." It is first during a dilation of s̄ = 50 mm., that the per cent. of men and women becomes even, after which, s̄ = 49.5 and lower, the per cent. of women grows considerably greater than that of men.

With men over fifty-nine or women over forty-nine years of age, the chest dilation (s̄) appears as high as 60 mm. only in isolated cases; with children three to fourteen years of age, on the contrary, quite often. The years of childhood mentioned stand before those of elder persons in this respect, of men arrived at sixty years, women at fifty years, and on the same level with middle-aged persons. The length of the body does not appear to have any particular effect on s̄.

Finally, it has constantly been shown that one cannot form any conclusions as to the condition of the lung apices from measurements taken on the mammillary plane. (Thorax measurements on the level with the nipples, as now used in life-insurance examinations, are therefore, in this respect, perfectly misleading.)

With Regard to Right- and Left-Handedness, or the Influence of Muscular Strength on the Dilation of the Chest.—If, as found by examination, the sound produced by breathing is often heard more distinctly (expirium one-tenth or more longer) from the right apex than from the left, depending—at least many times—on the greater capacity of the right lung, then one would be, perhaps, inclined to attribute to the same cause the fact that the difference between the dilation of the two lungs in the " subclavicular plane " is so often, in " sound " persons, etc., less for the left side, if only a fixed exception did not exist, namely, those who are left-handed (by which is particularly meant those who are stronger in the left hand), with whom the right lung shows the less difference instead.

If we consider the six cases of " from birth," not complicated, left-handedness which have come to notice, then we find Ds (where the measurements, *nota bene*, occurred regularly) less for Dx, and the fact has been the same with four not complicated, artificial cases of left-handedness (*i.e.*, the right hand stronger in the beginning, but weakened afterward through some disease, so that the left hand has become the stronger).

The reverse is true in a case of a right-handed person whose left arm appeared altogether too weak where Ds: Sr was unusually high; and also in a case of a left-handed person who became right handed because of myitis, where Ds was less for Sr instead of for Dx, as was the case with other left-handed persons.

Finally, in a case of " artificial " right-handedness, with Ds: Sr, after massage treatment had been given for a time, the cause for Dx manus was in a great degree removed and the left hand again became the stronger, thus reversing the difference and Ds: Dx resulting.

The above-mentioned case of left-handedness shows for itself the great influence right- or left-handedness has on the unilateral expansion of the chest, but still more, the power of the voluntary muscles of respiration appears, when considering the cases complicated by siderosis. In all the one hundred and twenty-eight siderosis cases, we see that Ds is, with right-handed persons: Dx, instead of Sr, as with those who are otherwise fully " sound," or with those with quantitatively equal changes in both lungs—depending, presumably, on the fact that right-handed persons take hold more with the right hand and so strain the muscles of respiration on the right side more, in consequence of which a greater dilation of that side of the chest takes place, with a correspondingly greater drawing in of particles of dust into the right lung, causing its activity to be soon reduced and reversed Ds to arise.

Such significance of the muscles is further proved by myitis, where it caused decreased dilation of the chest on the diseased side; by shrugging, where it caused increased dilation of the chest on the side lifted; by lameness, with the result of diminished dilation on the paralyzed side; stitch, or, if one may say so, enervation or pares for the time being, caused by pain, where diminished dilation on the diseased side was the result; one-sided straining or stiffening of one arm; increased dilation of this half of the chest, etc.

With Regard to the Accuracy of the Diagnosis.—It has been mentioned that the stethokyrtograph sometimes corrected the " diagnosis per aures," and especially the apparatus has proven itself superior to auscultation and percussion in showing the first stage of " siderosis; " and still further, it has several times shown " inverse differences," where not till later the reason for it was found; once after a couple of days by herpes zoster breaking out; another time, incipient consumption a year later, etc.

On the ground of previously mentioned examinations it is impossible to draw the conclusion that an " abnormal " Ds, which cannot be explained in any other way, in a person who has an otherwise perfectly healthy appearance, should be simultaneous with " predisposition to infiltration or consumption; " but other thorough examinations made at the same time, and not yet completed, speak for it, however, and in that case we should be able, with the stethokyrtograph's help, to form an opinion of great practical value, not only in a diagnostic-therapeutic respect, but still more in a prophylactic one.

With Regard to Pulmonary Tuberculosis Therapy.—The measurements of the stethokyrtograph have revealed the great influence of the muscles on the expansion of the chest. They have shown that myitis can diminish, and that massage as an antimyiticum can increase, the same. They have shown that a unilaterally stronger activity of the muscles of respiration extend their half of the chest relatively more, and that, vice versa, a weaker action proportionately less. It cannot well be denied that the more a chest dilates during respiration, the greater its excursions are, the greater will be the exchange of gases, not only for the lungs in their entirety, but also for every portion which distends appreciably, also the greater the oxygen supply; and in this case the blood-cells and serum, where gas exchange takes place—both of these struggling with all the power of self-defence of the organism against the host of bacilli with which they are in constant strife—should be strengthened and revivified all the more.

It is not enough that the two lungs do good work together, but each must do the same for itself and its own side, so that no " locus minoris resistentiæ " arises; for from analogy with the conditions of the other bodily functions, the energy and power of resistance of the cells decreases with their inactivity, when, on the other hand, a moderate straining increases their health and life.

Therefore, it is clear that the lungs must " all along the line " rise up to the common struggle for existence, for otherwise the more idle cell becomes weakened and an easy prey for the " tuberculous bacilli " which lie in wait for it; either it is now the lessened mobility and fitness of the cell, its decreased vital energy, or it is the lessened circulation of the blood, with decreased nourishment and transformation of the cells, and of intercellular substance which follows every decrease in activity, which promotes invasions.

When one notices that a portion of the lungs has been weakened, art must come to the rescue with the best methods, and where it is a question of mobility of a part of the body, Swedish medical gymnastics (the so called movement cure), (*nota bene*, if correctly employed), and massage have proved themselves to be nature's faithful allies. It is for this reason that a broad-minded therapy must include lung gymnastics (with special regard to the weaker side): also the methodical exercise and massage of the muscles of respiration where they are weak or diseased. It is for this reason that all treatment (though

here only those methods are dealt with which embrace measurements made, their results, and examinations of muscles) must also tend to a strictly individual theme which has regard in the first place to the strengthening of the respiratory muscles and removal of their weaknesses, and then, as a consequence of this, an increased chest dilation which does not cease after the *séances*, but if improvement in the condition of the lungs once begins, remains during the whole life.

WHAT ARE THE INDICATIONS FOR A VAGINAL EXAMINATION?[1]

By EDWIN B. CRAGIN, M.D.,

NEW YORK.

Believing that a large proportion of the members of this section are men in the practice of general medicine, it seems fitting that the writer should discuss a subject which, although it may seem prosaic, is certainly of importance, and that especially to the general practitioner. Fortunately the time is passed when a man who makes a vaginal examination, on a proper indication, is regarded as immodest or a charlatan. Diseases of the pelvic organs demand a correct diagnosis just as clearly as do diseases of the thoracic organs, and the man who neglects diseases of the one is as worthy of censure as the one neglecting the other.

By the use of the term "vaginal" examination, I do not mean to convey the idea that the vaginal is the only examination made at the time; it is usually a part of the bimanual. I speak of it only as one of the elements in a procedure which leads to a knowledge of the condition of the pelvic organs.

The object of this short paper is not to exhaust the list of indications for this examination, but to bring before the general profession the need of being on the alert for symptoms pointing to disease of the pelvic organs, and to refer chiefly to those which seem to be neglected.

For purposes of present discussion we will divide a woman's life into three periods:

1. Prior to marriage.
2. Married life during child-bearing period.
3. Near or subsequent to the menopause.

The indications for a vaginal examination in a young single woman are relatively few, yet they do exist and are imperative on a conscientious physician. One is often consulted by anxious mothers because their daughters do not menstruate as early as they themselves, or other members of the family, did. Here not only is a vaginal examination of the patient not indicative, but as a rule it is to be strongly deprecated. In general we may say that, leaving out of account illegitimate pregnancy, the only cases of amenorrhœa demanding vaginal examination are those of atresia of the genital tract, or symptoms of absence or lack of development of the generative organs when the question of marriage is at stake.

Mild cases of dysmenorrhœa do not call for a vaginal examination. Every honest gynecologist will admit that the longer a woman can go without the thought that she has trouble with her pelvic organs, the better it is for her; and for this same reason we sometimes meet with individuals neurotic, and inclined to be despondent, in whom, although we find on examination some slight departure from the normal, yet the best advice is that they receive no local treatment; and this advice we give, fearing that repeated examinations may fix her mind upon, and strongly color her whole horizon with the idea of uterine disease.

We all of us know how wretched a woman is who will sit in one's office and describe the pathology of the different diseases of each of her pelvic organs. This description need not be prolonged. The picture is familiar to most of us, and needs only to be kept in mind to warn us that, not without good reason, should we subject a patient to repeated vaginal examinations and treatment.

There are cases, however, of dysmenorrhœa of a more severe type, where the patient, in spite of all authorized medication, is confined to bed three or four days of every month, and with suffering almost indescribable. In such a case the writer believes not only that a vaginal examination is proper, but demanded. Such an examination is often best conducted under anæsthesia, for the purpose of avoiding both pain and mental shock. One other symptom in a young unmarried woman often indicates a vaginal examination, viz., an almost constant pain in the lower region of the back. We all know that this may be a symptom of many diseases, yet if the physician can find no anæmia, nephritis, or other general condition accounting for it, by all means let the patient have the benefit of a thorough pelvic examination, and have it ascertained whether her pelvic organs are displaced or not. As to whether this examination would best be conducted per vaginam, per rectum, or with the two combined, we shall not now discuss.

The next period concerning which I shall speak is *married life during the child-bearing period.* Perhaps the first indication for a vaginal examination will be pregnancy. It is a common practice among many physicians, even in this city, not to examine a pregnant patient until called to attend her in labor. The writer believes this practice to be wrong. Many a life both of mother and child has been exposed to peril which, had the condition of the pelvis and pelvic organs been previously known, might have been averted.

Pregnancy itself constitutes an indication for a vaginal examination, and long before the time of the expected labor the pelvis and its contents should be carefully examined. Nor does the indication for a vaginal examination cease with the parturition. Before the parturient is discharged from the care of her physician, it should be the duty of that physician, after having thoroughly cleansed his hands, to carefully examine the position and condition of the patient's pelvic organs. This examination is perhaps even more demanded in the lower classes of society than in the higher, for at a time when, by the stern necessities of life, the former are obliged to resume their usual household duties, the uterus is often large, flabby, and easily displaced. Before the physician makes his last obstetric visit on such a case as this, he should ascertain whether or not the uterus lies in the hollow of the sacrum, and if found there, an attempt should be made to replace and maintain it in proper position until involution is complete.

A very large number of the patients who present themselves to me at the Roosevelt Out-patient Department, come suffering with posterior displacements of the uterus, and of these a large proportion can be traced to a puerperium in which this displacement has occurred, and not being discovered, has been allowed to continue until the uterus has become fixed, the patient subjected to months of suffering, and weeks or even months may be required before the condition can be relieved. Most of this could have been prevented by due care following parturition. Preventive medicine is the key-note of our profession to day, and of this prophylaxis preventive gynecology should form a prominent part.

Nor should the responsibility of a physician, in a case of obstetrics, cease with what might be called his last obstetric visit. I believe that in the near future the physician will consider it his duty to examine each obstetric case at the end of two or three months after her confinement, to ascertain by vaginal examination not only the question of the uterus being in its proper position, but also the condition of the patient's cervix; and whether at the expiration of lactation a trachelorrhaphy will not be indicated before her nervous system has become undermined and perhaps malignant disease has started. If we take these precautions in our own obstetric cases, we must be on the lookout for symptoms with similar indications in patients who were formerly in the hands of others.

[1] Read before the Section on Obstetrics and Gynecology of the New York Academy of Medicine, January 25, 1894.

The discussion as to whether a cervical laceration needs operation will not concern us here; we are all pretty thoroughly agreed that *bad lacerations need repair.*

Another symptom in which a vaginal examination is often neglected is menorrhagia or metrorrhagia. Many a case has come under the writer's observation where a patient has been allowed to bleed for weeks, perhaps for months, while the physician soothed his conscience by prescribing some ergot or hydrastis, or by telling the patient to come and be examined when her flow ceases; but never taking the trouble to ascertain by vaginal examination whether the patient has a polypus, a cancer, or needs to be curetted. There is ground for great improvement in this mode of practice. Many a patient's health has been ruined, many a valuable opportunity has been lost, by just such neglect of the vaginal examination and the information it would convey.

While the previous indications for the vaginal examination are important and their neglect greatly to be deplored, they all shrink into insignificance when compared with the indications which are more common during the last period of life, of which I shall speak, viz., *Near or subsequent to the menopause.* I refer to symptoms of malignant disease. It is unfortunate for the profession, and still more unfortunate for the patient, that the impression is wide spread that floodings at the menopause are normal, and therefore need no attention. The soothing explanation of "only the change of life" has been the funeral dirge of many a death from cancer of the uterus.

Another unfortunate circumstance for both physician and patient is the fact that uterine cancer, in its early and operable stage, is often associated with no pain. Being handicapped by these two circumstances, the physician must be more and more impressed with the fact that he must be ever on the alert, especially at this period of life, for symptoms which might mean cancer. It is not enough that these symptoms may be explained on other grounds; if there is the slightest suspicion, from the appearance of an irregular flow or discharge, that the patient might possibly be suffering from incipient malignant disease, a vaginal examination should be made, and malignancy if possible excluded. Why is it that so many more correct diagnoses of ectopic gestation are now made than formerly? It is simply because the profession is now on the lookout for that condition. This ought to be more and more the case in the search for cancer. Mistakes will be made and cases diagnosed malignant which are not, just as cases are diagnosed ectopic gestation which are not; but better far an error in this direction than in neglect till past help. It is the general impression that in early life we need have very little fear of malignant uterine disease, yet even here we find we are not safe. It is only a short time since the writer had under his observation a patient suffering with inoperable malignant disease of cervix and vagina, and who died before she reached the age of thirty. It is only by bearing in mind the fact that uterine cancer is possible at almost any age from puberty till death, that we can appreciate the importance of a vaginal examination, when presented with symptoms which are associated with malignant disease. Certainly in a patient who has passed the menopause and then experiences a bloody flow, not a day should elapse before an attempt is made at an accurate diagnosis.

This need of alertness in search for malignant disease will apply even more to the general practitioner than to the specialist. It is the family physician who is usually first consulted, and he it is who usually has the privilege of an early diagnosis.

The technique of operation for uterine cancer seems well-nigh perfect, but there is still a field, a large field, for improvement in early diagnosis. This is where we hope we are to make advance in the near future. The writer this evening does not expect that he has presented anything new. The object of the paper was entirely practical, viz., to impress upon the profession the need of alertness for indications for a vaginal examination.

62 West Fiftieth Street.

Clinical Department.

ENTEROLITH MISTAKEN FIRST FOR APPENDICITIS, AND THEN FOR CARCINOMA.[1]

By A. F. JONAS, M.D.,

Professor of Surgery, Omaha Medical College, Omaha, Neb.

There seems to be a uniformity of opinion as to the technique of the operation for appendicitis, or perityphlitic disease. But opinions still widely differ as to the time and indications for the operation, while no one seems to dispute the difficulty in making the diagnosis in any given case. Therefore every unusual experience should be recorded in order that we may obtain and utilize every diagnostic aid, that we may differentiate with certainty every pathological lesion located in the right iliac fossa and its vicinity, and particularly that we may recognize with more positiveness that affection dreaded by both physician and patient, perforative appendicitis, and typhlitis.
